We present a measurement of the fraction $f_\pm$ of right-handed $W$ bosons produced in top quark decays, based on a candidate sample of $t\bar{t}$ events in the lepton+jets decay mode. These data correspond to an integrated luminosity of $230 \text{ pb}^{-1}$, collected by the D0 detector at the Fermilab Tevatron $p\bar{p}$ Collider at $\sqrt{s} = 1.96 \text{ TeV}$. We use a constrained fit to reconstruct the kinematics of the $t\bar{t}$ and decay products, which allows for the measurement of the leptonic decay angle $\theta^\ell$ for each event. By comparing the $\cos\theta^\ell$ distribution from the data with those for the expected background and signal for various values of $f_\pm$, we find $f_\pm = 0.00 \pm 0.13^{\text{stat}} \pm 0.07^{\text{syst}}$. This measurement is consistent with the standard model prediction of $f_\pm = 3.6 \times 10^{-4}$.

DOI: 10.1103/PhysRevD.72.011104  PACS numbers: 14.65.Ha, 14.70.Fm, 12.15.Ji, 12.38.Qk
The top quark is by far the heaviest of the known fermions and is the only one that has a Yukawa coupling of order unity to the Higgs boson in the standard model. The top quark is also unique in that it decays through the electroweak interaction before it can hadronize. In the standard model, the top quark decays via the $V-A$ charged current interaction, and almost always to a $W$ boson and $b$ quark. We search for evidence of new physics in the $t \rightarrow Wb$ decay by measuring the helicity of the $W$ boson. The $W$ bosons produced from these decays are predominantly in either a longitudinal or a left-handed helicity state with fractions $f_0$ and $f_-$, respectively. For any linear combination of $V$ and $A$ currents at the $tWb$ vertex [1],

$$f_0 = \frac{m_t^2}{2M_W^2 + m_t^2 + m_b^2} = 0.703 \pm 0.012,$$

where $m_t$ is the mass of the top quark for which we use $175 \pm 5$ GeV (consistent with the world average [2]), $M_W$ is the mass of the $W$ boson, and $m_b$ is the mass of the bottom quark. In this analysis, we fix $f_0$ at 0.7 and measure the positive helicity fraction $f_+$. In the standard model, $f_+$ is suppressed by a factor of $(m_b/m_t)^2$ and is predicted at next-to-leading order to be $3.6 \times 10^{-4}$ [3]. A measurement of $f_+$ that differs significantly from this value would be an unambiguous indication of new physics. For example, an $f_+$ value of 0.3 would indicate a purely $V+A$ charged current interaction. A possible theoretical model that includes a $V+A$ contribution at the $tWb$ vertex is an $SU(2)_L \times SU(2)_R \times U_Y(1)$ extension of the standard model [4]. Direct measurements of the longitudinal fraction found $f_0 = 0.91 \pm 0.39$ [5] and $f_0 = 0.56 \pm 0.31$ [6]. A recent direct measurement of $f_+$ set a limit of $f_+ < 0.18$ at the 95% C.L. [7]. In addition, measurements of the $b \rightarrow s\gamma$ decay rate have indirectly limited the $V+A$ contribution in top quark decays to less than a few percent [8]. However, direct measurements of the $V+A$ contribution are still necessary because the limit from $b \rightarrow s\gamma$ assumes that the electroweak penguin contribution is dominant.

The angular distribution $\omega$ of the $W$ boson decay products with weak isospin $I_3 = -1/2$ (charged lepton or $d$, $s$ quark) in the rest frame of the $W$ boson can be described by introducing the angle $\theta^*$ with respect to the top quark direction [1]:

$$\omega(\cos \theta^*) = \frac{3}{4} (1 - \cos^2 \theta^*) f_0 + \frac{3}{8} (1 - \cos \theta^*)^2 f_- + \frac{3}{8} (1 + \cos \theta^*)^2 f_+.$$  

(2)

Because of backgrounds and reconstruction effects, the distribution of $\cos \theta^*$ we observe differs from $\omega(\cos \theta^*)$. However, the shape of the measured $\cos \theta^*$ distribution depends on $f_+$ and this dependence can be used to measure $f_+$. We do this by selecting a data sample enriched in $t\bar{t}$ events, reconstructing the four vectors of the top quarks and their decay products using a kinematic fit, and then calculating $\cos \theta^*$. This distribution in $\cos \theta^*$ is compared with templates for different $f_+$ values using a binned maximum likelihood method.

The D0 detector [9] comprises three main systems: the central-tracking system, the calorimeters, and the muon system. The central-tracking system is located within a 2 T solenoidal magnet. The next layer of detection involves three liquid-argon/uranium calorimeters: a central section (CC) covering pseudorapidities [10] $|\eta| \leq 1$, and two end calorimeters (EC) extending coverage to $|\eta| = 4$, all housed in separate cryostats. The muon system is located beyond the calorimetry, and consists of a layer of tracking detectors and scintillation trigger counters before 1.8 T toroids, followed by two more similar layers after the toroids.

This measurement uses a data sample recorded by the D0 experiment corresponding to $230 \pm 15$ pb$^{-1}$ of $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV. We consider $t\bar{t}$ candidate events selected in the lepton+jets channel where one of the $W$ bosons from $t$ or $\bar{t}$ decays into an electron or muon and a corresponding neutrino and the other $W$ boson decays hadronically. The final state is therefore characterized by one charged lepton ($e$ or $\mu$), at least four jets (two of which are $b$ jets), and significant missing transverse energy ($E_T$).

Two separate analyses are performed and the results are combined. One analysis uses kinematic information to select $t\bar{t}$ events ("kinematic analysis") and the other uses $b$ jet identification as well as kinematic information in order to improve the signal to background ratio ("$b$-tagged analysis"). A $b$ jet is identified by a displaced secondary vertex close to an associated jet [11]. The kinematic analysis vetoes $b$-tagged events to simplify the combination of results with the $b$-tagged analysis. In both analyses, selected events arise predominantly from three sources: $t\bar{t}$ production, $W+$ jets production, and multijet production where one of the jets is misidentified as a lepton and spurious $E_T$ appears due to mismeasurement of the transverse energy in the event.

The event selection [12] requires an isolated lepton ($e$ or $\mu$) with transverse momentum $p_T > 20$ GeV, no other lepton with $p_T > 15$ GeV in the event, $E_T > 20$ GeV, and at least four jets. Leptons are categorized in two classes, “loose” and “tight,” the latter being a subset of the first. Loose electrons are required to have $|\eta| < 1.1$ and are identified by their energy deposition and isolation in the calorimeter, their transverse and longitudinal shower shapes, and information from the tracking system. For tight identification, a discriminant combining the above information must be consistent with the expectations for a high-$p_T$ isolated electron. Loose muons are identified using the information from the muon and the tracking systems. They are required to have $|\eta| < 2.0$ and to be isolated from jets. Tight muons must also pass stricter
samples can be used to create reconstructed using a kinematic fit which is subject to the criterion in the present significantly reduces the background contamination for signal events.

The top quark and the W boson four-momenta are reconstructed using a kinematic fit which is subject to the following constraints: two jets must form the invariant mass of the W boson, the lepton and the boson together with the neutrino component must form the invariant mass of the W boson, and the masses of the two reconstructed top quarks must be equal to 175 GeV. The component of the neutrino is reconstructed by exploiting the fact that the masses of the two top quarks are both set to be 175 GeV, and solving the resulting quadratic equation for . In the case where the two solutions lead to different results of the kinematic fit, the one with the lower (of the fit) is kept. Among the 12 possible jet combinations, the solution with the minimal (from the kinematic fit is chosen; Monte Carlo studies show this yields the correct solution in about 60% of all cases.

The signal events for seven different values of , , , , , , 0.30 in steps of 0.05, are generated with the ALPGEN Monte Carlo (MC) program [14] for the parton-level process (leading order) and PYTHIA [15] for simulation of subsequent hadronization. The mass of the top quark is set to . As the interference term between and is suppressed by the small mass of the quark and is therefore negligible [16], these samples can be used to create templates for any value by a linear interpolation of the templates. All seven templates from these samples are normalized to unit area and a linear fit to the contents of each bin as a function of is performed. This procedure effectively averages over statistical fluctuations in the generated MC samples, thus providing a more precise model of the distribution. The MC samples used to model events with bosons produced in association with jets (W+jets) are also generated with ALPGEN, requiring the W boson to decay leptonically. The factorization scale is set to .

To determine the number of multijet background events, we compare samples selected with loose and tight lepton. Going from loose to tight samples decreases the number of events from to . The relative selection efficiency between the loose and the tight lepton criteria is different for true leptons () and jets faking an isolated lepton () . We use these efficiencies, known from data control samples [12], to estimate the number of multijet background events: . The kinematic analysis calculates for each bin in the distribution from the data sample to obtain the shape of the multijet templates. For the -tagged analysis, the multijet template is formed from data events after the event selection except that the leptons are required to satisfy the loose and fail the tight criteria.

To discriminate between pair production and background, a discriminant is built [12] using input variables which exploit the differences in event topology: (defined as the scalar sum of the jet values), the minimum dijet mass of the jet pairs, the from the kinematic fit, the centrality (defined as where is the sum of the jet energies) [17], (defined as the distance in space, where is the azimuthal angle, between the closest pair of jets multiplied by the of the lowest- jet in the pair and divided by the transverse energy of the reconstructed W boson) [13], and aplanarity and sphericity (calculated from the four leading jets and the lepton). The last two variables characterize the event shape and are defined, for example, in Ref. [18]. Only the four leading jets in are considered in computing these variables to reduce the dependence on systematic effects from the modeling of soft radiation and underlying event processes. All of these variables are used for the discriminant in the kinematic analysis. Only , centrality, the minimum dijet mass, and are used in the analysis. The discriminant is built separately for the kinematic and -tagged analyses, using the method described in Refs. [12,13]. The distributions of signal (S) and background (B) events in each of the above variables are normalized to unity. For each variable, we fit a polynomial to the logarithm of as a function of . The discriminant is defined as

\[ \mathcal{D}(v_1, v_2, \ldots) = \frac{\exp\left[\sum_{i} \ln(S(v_i)/B(v_i))\right]}{\exp[\ln(S(v_1)/B(v_1))] + 1} \]  

We select events for which \( \mathcal{D} > 0.6 \) in the kinematic analysis, and \( \mathcal{D} > 0.25 \) in the -tagged analysis. These values are chosen to minimize the expected statistical uncertainty in the measurement of as determined by simulations of the analysis.

We then perform a binned maximum likelihood fit to compare the observed distribution in the data to the sum

of the distributions expected from $t\bar{t}$, $W+$ jets, and multijet events. The number of multijet events is constrained to a Poisson distribution with mean $N_m$. The likelihood is then maximized with respect to the number of $t\bar{t}$, $W+$ jets, and multijet events. We multiply these numbers by the efficiency for each type of event to pass the $D$ selection to determine the composition of the sample used for measuring $\cos\theta^*$. Table I lists the composition of each sample as well as the number of observed events in the data. The $\cos\theta^*$ distribution observed in data after the full selection is shown in Fig. 1 for the kinematic and in Fig. 2 for the $b$-tagged analysis.

A binned maximum likelihood fit of signal and background $\cos\theta^*$ templates to the data was used to measure $f_+$. We compute the binned Poisson likelihood $(L(f_+))$ of the data to be consistent with the sum of signal and background templates, normalized to the numbers given in Table I, at each of the seven chosen $f_+$ values. In both analyses, a parabola is fit to the $-\ln[L(f_+)]$ points to determine the likelihood as a function of $f_+$.

Systematic uncertainties are evaluated in ensemble tests by varying the parameters (see Table II) which can affect the shape of the $\cos\theta^*$ distributions or the relative contribution from the three sources ($t\bar{t}$, $W+$ jets and QCD). Ensembles are formed by drawing events from a model with the parameter under study varied. These are compared to the standard $\cos\theta^*$ templates in a maximum likelihood fit. The average shift in the resulting $f_+$ value is taken as the systematic uncertainty and is shown in Table II. The total systematic uncertainty is then taken into account in the likelihood by convoluting the latter with a Gaussian with a width that corresponds to the total systematic uncertainty.

The top quark mass and the jet energy calibration (JEC) are the leading sources of systematic uncertainty. The mass of the top quark has been varied by $\pm 5$ GeV with respect to $m_t = 175$ GeV and the JEC by $\pm 1\sigma$ around the nominal value. The statistical uncertainty on the $\cos\theta^*$ templates has been taken as a systematic uncertainty. It is estimated by fluctuating them according to their statistical uncertainty. Uncertainties in the modeling of the $b$-tag algorithm lead to uncertainties in the flavor composition of the $W+$ jets background and in the $\cos\theta^*$ distribution itself due to the $p_T$ and $\eta$ dependence of the $b$-tag algorithm [11]. An uncertainty in the flavor composition translates into a different shape of the $\cos\theta^*$ distribution and a difference in the signal to background ratio. In order to estimate the systematic uncertainty due to gluon radiation in $t\bar{t}$ events, an alternative signal sample of $t\bar{t}+$ jet has been generated with ALPGEN, and mixed with the default $t\bar{t}$ sample using the leading order cross sections for both processes. Effects of the choice of factorization scale $Q$ in the generation of the $W+$ jets events have been evaluated by using a sample where $Q^2 = \langle p_T^2 \rangle$ [14]. There is a systematic uncertainty due to the final sample composition obtained by the fit to the discriminant $D$. The kinematic

analysis treats this uncertainty as a statistical uncertainty and includes it in the definition of the likelihood as described in Ref. [19] while in the $b$-tagged analysis this uncertainty is studied by changing the compositions within their errors. The difference found between the input $f_+$ value and the reconstructed $f_+$ value in ensemble tests is taken as systematic uncertainty on the calibration of the analysis.

The result of the maximum likelihood fit to the $\cos\theta^*$ distribution observed in the data is shown in Figs. 3(a) and 3(b) for the kinematic and $b$-tagged samples, respectively. The statistical uncertainties from the two individual analyses are 0.22 for the kinematic and 0.17 for the $b$-tagged analysis. The $\ln L$ curves for the kinematic and $b$-tagged measurements are combined, as shown in Fig. 3(c). The systematic uncertainties are assumed to be fully correlated except for the systematics on calibration of the individual analyses which are uncorrelated, and the Monte Carlo model systematics which are partially correlated. Assuming a fixed value of 0.7 for $f_0$, the combined result for $f_+$ is

$$f_+ = 0.00 \pm 0.13\text{(stat)} \pm 0.07\text{(syst)}.$$  (4)

The observed combined statistical uncertainty (0.13) is in good agreement with the expectation (0.12) inferred from ensemble tests. We also calculate a Bayesian confidence interval (using a flat prior distribution which is nonzero only in the physically allowed region of $f_+ = 0.0 - 0.3$) which yields

$$f_+ < 0.25 \text{ at 95\% C.L.}$$  (5)

The $W$ boson positive helicity fraction $f_+$ that we have measured in $t\bar{t}$ decays in the lepton+jets channel is consistent with the standard model prediction of $f_+ = 3.6 \times 10^{-4}$ [3].
