An improved measurement of the $B^0_s$ lifetime

OPAL Collaboration

Abstract

This letter presents an updated measurement of the lifetime of the $B_s^0$ meson using 3.6 million hadronic $Z^0$ decays recorded by the OPAL detector at LEP from 1990 to 1994. A sample of $B_s^0$ decays is obtained using $D_s^-\ell^+\nu$ combinations, where the $D_s^-$ is reconstructed in either the $\phi\pi^-$ or $K^{*0}K^-$ decay mode. From $79 \pm 13$ $D_s^-\ell^+\nu$ combinations attributed to $B_s^0$ decays in this data sample, we measure

$$\tau(B_s^0) = 1.54^{+0.22}_{-0.21} \pm 0.06 \text{ ps},$$

where the errors are statistical and systematic, respectively.

1. Introduction

The lifetimes of b-flavored hadrons are related to both the strength of the b quark coupling to c and u quarks, and the dynamics of b hadron decay. The spectator model assumes that the light quarks in b and c hadrons do not affect the decay of the heavy quark, and thus predicts the lifetimes of all b hadrons to be equal. For charm hadrons this prediction is inaccurate; the measured $D^+$ lifetime is approximately 2.5 times that of the $D^0$ and more than twice that of the $D_s^+ [1]$. More sophisticated models predict that the differences among b hadron lifetimes should be much smaller than those in the charm system, because of the larger mass of the b quark [2,3]. These models predict a difference in lifetime between the $B^+$ and $B^0$ meson of several percent, and between the $B_s^0$ and $B^0$ meson of about 1% [3]. OPAL [4], and other collaborations [5], have published measurements of the $B_s^0$ lifetime.

In this letter, we present an updated measurement of the lifetime of the $B_s^0$ meson, which supersedes our previous measurement [4]. The two decay channels used are

$$B_s^0 \rightarrow D_s^-\ell^+\nu \ (X) \quad B_s^0 \rightarrow D_s^-\ell^+\nu \ (X)$$

where $\ell$ is an electron or a muon. The proper decay time is determined on an event-by-event basis using measured decay lengths and estimates of the $B_s^0$ energy. The following sections describe the OPAL detector, the selection of $B_s^0$ candidates, the vertex topology of the events, the determination of the $B_s^0$ decay length, the estimation of the $B_s^0$ energy, the lifetime fit, the results, and the systematic errors.

2. The OPAL detector

The OPAL detector is described in Ref. [6]. The central tracking system is composed of a precision vertex drift chamber, a large volume jet chamber surrounded by a set of chambers to measure the $z$-coordinate ($z$-chambers) and, for the majority of the data used in this analysis, a high-precision silicon microvertex detector. These detectors are located inside

1. Also at TRIUMF, Vancouver, Canada V6T 2A3.
2. Royal Society University Research Fellow.
3. In this paper, charge conjugate modes are always implied. Also, unless otherwise noted, $K$ and $\pi$ always refer to charged particles.
a solenoidal coil. The detectors outside the solenoid consist of a time-of-flight scintillator array and a lead glass electromagnetic calorimeter with a presampler, followed by a hadron calorimeter consisting of the instrumented return yoke of the magnet, and several layers of muon chambers. Charged particles are identified by their specific energy loss, dE/dx, in the jet chamber. Further information on the performance of the tracking and dE/dx measurements can be found in Ref. [7].

3. \( B_s^0 \) candidate selection

This analysis uses data collected during the 1990-1994 LEP running periods at center-of-mass energies within \( \pm 3 \text{GeV/c}^2 \) of the \( Z^0 \) mass. After the standard hadronic event selection [8] and detector performance requirements, a sample of 3.6 million events is selected. Jets are defined using charged tracks and electromagnetic clusters not associated with a charged track. These are combined into jets using the scaled invariant mass algorithm with the E0 recombination scheme [9] using \( \chi^2_{\text{cut}} = 0.04 \). Tracks arising from identified secondary vertices due to decays of \( \Lambda, K_s^0 \) or \( \gamma \) conversions are excluded from the \( B_s^0 \) candidate selection.

3.1. \( D_s^- \rightarrow K^+K^-\pi^- \) selection

In this analysis, \( D_s \) candidates are reconstructed in two modes. The first is \( D_s^- \rightarrow K^{*0}K^- \) in which the \( K^{*0} \) decays into a \( K^+\pi^- \). The second is \( D_s^0 \rightarrow \phi\pi^- \) where the \( \phi \) subsequently decays into \( K^+K^- \). When searching for \( D_s \) candidates, all combinations of tracks which are within a single jet and constitute the appropriate charge combination are considered.

Particle identification is used to reduce the combinatorial background. For each track forming the KK\( \pi \) combination, the measured dE/dx is compared with the expected value, and the probability that it is consistent with a given mass assignment is required to be greater than 1%. If the observed energy loss of each kaon candidate is greater than the mean dE/dx expected for a kaon, it is required that the product of the two dE/dx probabilities be greater than 0.02. In order to improve the mass and decay length resolutions, at least two of the three candidate tracks are required to have good \( \theta \) measurements either from the \( z \)-chambers or from a measurement of the track's endpoint as it exits the main jet chamber. The KK\( \pi \) combination is required to have a momentum greater than 9 GeV/c in order to reduce random track combinations.

For the \( K^{*0}\pi^- \) mode, the invariant mass of the KK\( \pi \) combination taken to be the \( K^{*0} \) is required to satisfy \( 0.845 < m_{KK} < 0.945 \text{GeV/c}^2 \). To minimize the possibility of mistaking a \( D^- \rightarrow K^{*0}\pi^- \) decay for our desired signal, the measured dE/dx of the kaon candidate directly from the \( D_s \) decay must be at least one standard deviation below the mean dE/dx that is expected for a pion. This track must also have a momentum greater than 2 GeV/c in order to be in the momentum region of good kaon-pion separation. If the observed energy loss of this track is greater than the mean expected for a kaon, it must have a dE/dx probability assuming a kaon hypothesis that is greater than 5%. In the \( \phi\pi \) mode, the \( K^+K^- \) invariant mass is dominated by detector resolution and is required to satisfy \( 1.005 < m_{KK} < 1.035 \text{GeV/c}^2 \).

The differences between the angular distributions of \( D_s \) decays and those of random track combinations are used to suppress the combinatorial background. The \( D_s \) is a spin-0 meson and the final states of both decay modes consist of a spin-1 (\( \phi \) or \( K^{*0} \)) meson and a spin-0 (\( \pi^- \) or \( K^- \)) meson. The \( D_s \) signal is expected to have no dependence on \( \cos \theta_p \), where \( \theta_p \) is the angle in the rest frame of the \( D_s \) between the spin-0 meson direction and the \( D_s \) direction in the lab frame. However, the \( \cos \theta_p \) distribution of random combinations peaks in the forward and backward directions. It is therefore required that \( |\cos \theta_p| < 0.8 \) (0.9) for the \( K^+K^- \) (\( \phi\pi \)) mode. The angular distribution of \( \theta_v \), the angle in the rest frame of the spin-1 meson between the direction of the final state kaon from the decay of the spin-1 meson and the \( D_s \) direction, is proportional to \( \cos^2 \theta_v \) for \( D_s \) decays. The \( \cos \theta_v \) distribution of the random KK\( \pi \) combinations in the data is, however, approximately flat. Therefore it is required that \( |\cos \theta_v| > 0.4 \).
3.2. \( \text{D}_s^- \ell^+ \) selection and decay length determination

Once a KK\( \pi \) combination that satisfies the D\(_s\) candidate selection is found, a search is performed to find a lepton of opposite charge in the same jet. Electron candidates are identified using an artificial neural network based on 12 measured quantities from the electromagnetic calorimeter and the central tracking detector \([10]\). Electron candidates identified as arising from photon conversions are rejected \([11]\). Muons are identified by associating central detector tracks with track segments in the muon detectors and requiring a position match in two orthogonal coordinates \([11]\). Lepton candidates are required to have a momentum greater than 2 GeV/c for electrons and 3 GeV/c for muons. The leptons must have a transverse momentum with respect to the associated jet direction of at least 0.8 GeV/c. In addition it is required that the lepton candidate track be precisely measured by either the silicon vertex detector or the vertex drift chamber.

In order to suppress background, it is required that the mass of the KK\( \pi \ell \) combination be between 3.2 and 5.5 GeV/c\(^2\), and the momentum of this combination must be at least 17 GeV/c. The cosine of the opening angle between the KK\( \pi \ell \) and lepton directions must be greater than 0.4.

Three vertices – the beam spot, the B\(_s^0\) decay vertex and the D\(_s\) decay vertex – are reconstructed in the x–y plane. The beam spot is measured using charged tracks in the OPAL data with a technique that follows any significant shifts in the beam spot position during a LEP fill \([12]\). The intrinsic width of the beam in the y direction is taken to be 8 \(\mu\)m, from considerations of LEP beam optics. The width in the x direction is measured directly and found to vary between 100 \(\mu\)m and 160 \(\mu\)m, depending on the LEP optics.

The D\(_s\) vertex is formed from a fit using the KK\( \pi \) candidate tracks. The B\(_s^0\) decay vertex is formed by extrapolating the KK\( \pi \) momentum vector from its decay vertex to the intersection with the lepton track. The D\(_s\) decay length is the distance between these two decay vertices. The B\(_s^0\) decay length is found by a fit between the beam spot and the reconstructed B\(_s^0\) decay vertex using the direction of the KK\( \pi \ell \) momentum vector as a constraint. The two-dimensional projections of the B\(_s^0\) and D\(_s\) decay lengths are converted into three dimensions using the polar angles reconstructed using the momenta of the KK\( \pi \ell \) and KK\( \pi \), respectively. Typical decay lengths are about 0.25 cm for B\(_s^0\) and 0.11 cm for D\(_s\) mesons. The corresponding typical decay length errors are about 0.03 and 0.09 cm.

Additional criteria are used to select KK\( \pi \) combinations suitable for precise decay length measurements. In order to ensure that the KK\( \pi \) candidate tracks come from a common vertex, the \(\chi^2\) of the vertex fit is required to be less than 10 (for 1 degree of freedom). The candidate must also have a decay length error less than 0.3 cm. Using the measured decay length and momentum of the KK\( \pi \) combination, the proper decay time of the D\(_s\) candidate is determined. This is required to be within two standard deviations of the range from zero to four D\(_s\) mean lifetimes. Finally, the decay length error of the reconstructed B\(_s^0\) candidate must be less than 0.2 cm.

3.3. Results of D\(_s^- \ell^+ \) selection

The KK\( \pi \) invariant mass distribution for all K\(^+\)K\(^-\)\( \pi^- \ell^+ \) candidates is shown in Fig. 1. An unbinned likelihood fit to the measured KK\( \pi \) invariant mass of the D\(_s\) candidates is performed. The KK\( \pi \) mass distribution is parameterized as the sum of a linear term to account for random combinatorial background, a Gaussian function which describes the mass peak of the reconstructed D\(_s\) signal, and another Gaussian to account for a D\(^-\) \(\rightarrow\) K\(^+\)K\(^-\)\( \pi^-\) contribution. This last term has a mean fixed to the D\(^-\) mass of 1869.3 MeV/c\(^2\) \([1]\) and the width con-
strained to be the same as that of the \( D_s \) peak. It is included in order to avoid biasing the estimate of the combinatorial background. The fit yields a \( D_s \) mass of \( 1.967 \pm 0.004 \text{ GeV/}c^2 \), a width (\( \Gamma \)) of \( 22 \pm 3 \text{ MeV/}c^2 \) and a total of \( 84 \pm 13 \) candidates. The fitted combinatorial background fraction is \( 0.43 \pm 0.05 \) for the \( 2\sigma \) interval about the fitted \( D_s \) mass.

By integrating the tail of the peak due to the \( D^- \to K^+K^-\pi^- \) decays in this \( D_s \) signal region, the contamination from this source is found to be negligible. No peak is observed at the \( D_s \) mass in the wrong sign \( D_s^-e^- \) sample (see Fig. 1). The probability that a given event comes from combinatorial background is calculated as a function of its \( KKn \) invariant mass using the results of the fit to the mass distribution for use in the \( B \to D_s^0 \ell^+ \) lifetime fit discussed below.

### 3.4. Backgrounds to the \( B^0_s \to D_s^-\ell^+ \) signal

Potential sources of backgrounds to the \( B^0_s \to D_s^-\ell^+ \) signal that have been considered include decays of other \( B \) hadrons that can yield a final state \( D_s\ell \) combination and charm hadrons that are mis-identified as a \( D_s \) meson. Other sources are \( D_s \) mesons combined with a hadron that has been mis-identified as a lepton, and random associations of \( D_s \) mesons with genuine leptons.

The signal events mentioned above include properly reconstructed \( D_s\ell \) combinations that do not arise from \( B^0_s \) decay. Two decay modes of \( B^0 \) and \( B^+ \) mesons have been considered: \( B \to D_s^+D(X) \), \( D \to \ell^-X \) (where \( D \) is any non-strange charm meson) and \( B \to D_s^+K\ell^+\nu(X) \), where \( K \) is any type of kaon. For the signal mode, the production branching fraction \( \text{Br}(B \to D_s^+D(X)) \cdot \text{Br}(D_s^+ \to D_s\ell) = 2.8 \pm 0.7\% \) is used [13]. Monte Carlo simulations of both a standard multihadronic sample and the specific decay modes of interest are used to determine the selection efficiencies for these modes relative to that of the signal mode. These samples were produced using the JETSET 7.3 parton shower Monte Carlo generator [14] with the fragmentation function of Peterson et al. [15] for heavy quarks, and then passed through the full OPAL detector simulation package [16].

For the background, the probability for a bottom quark to form a \( B^+ \) or \( B^0 \) meson is \( 0.81 \pm 0.11 \) [17]. For the \( B \to D_s^-K\ell^+\nu X \) mode, a theoretical estimate [18] that predicts an upper limit of \( 0.025 \cdot \text{Br}(B \to D_s\ell) \) is used. This is slightly below the present measured upper limit [1]. For the other background mode, it is noted that \( \text{Br}(B \to D_sX) = 0.085 \pm 0.011 \) [1] and assumed that all of the modes of \( B \to D_sX \), aside from the assumed \( B \to D_sK\ell\nu X \) contribution, are of the form \( B \to D_sDX \). This has been shown to be the case for two-body decays of the \( B \) mesons to a \( D_s \) [1], and we assume the same for those modes with three or more particles in the final state. The fraction of \( B \to D_sX \) decays that are in a two-body final state is determined by correcting for the assumed presence of the \( B \to D_sK\ell\nu X \) mode. It is assumed that the average branching fraction of the \( D_s \) meson to \( e^- \) and \( \mu^- \) combined is \( 0.20 \pm 0.05 \), and the fraction of these \( D_s \) mesons which come from orbitally excited states is estimated to be \( 0.3 \pm 0.05 \). Thus, with an observed signal of \( 84 D_s^-\ell^+ \) pairs, \( 1.9 \pm 0.8 \) candidates from \( B \to D_s^-K\ell^+\nu X \) decays, and \( 2.8 \pm 2.6 \) events in the mode \( B \to D_s^+DX \), \( D_s^- \to \ell^-X \) are expected.

The background from events where the three \( KKn \) candidate tracks come either from the same fully reconstructed charm hadron for which a pion or a proton has been mis-identified as a kaon, or from a partially reconstructed charm hadron, was estimated using simulated events. For these candidates the \( KKn \) invariant mass distribution around the \( D_s \) mass is similar to that of the combinatorial background. Such events are therefore considered to be included in the combinatorial background fraction.

The background caused by a \( D_s \) which has been combined with a hadron that has been mis-identified as a lepton can be estimated by fitting the \( KKn \) mass spectrum of wrong sign combinations \( (K^+K^-\pi^-\ell^-) \). This assumes that random combinations are equally likely to have right and wrong charge correlations. Using the higher statistics available when \( D_s^+\ell \) correlations are considered it is found that this background is less than \( 1\% \) [10] of that sample and this contribution is therefore neglected. Similarly, no signal is observed when this is repeated with the \( D_s^-\ell^- \) candidates of this analysis.

Finally the background from random associations of \( D_s \) mesons with genuine leptons was estimated using simulated data to contribute less than one event to our
The production of orbitally excited strange D mesons will not contribute to our sample as these are expected to decay to a DK pair, and not a Ds.

The likelihood function for observing a particular decay length of a $B_s^0$ meson may now be parameterized in terms of the measurement error of the decay length, the $D_s\ell$ invariant mass and momentum, and the assumed lifetime. Specifically, this function is given by the convolution of three terms: an exponential whose mean is the $B_s^0$ lifetime, the boost distribution as given by the values of the observed $D_s\ell$ mass and momentum, and a Gaussian resolution function whose width is the measured decay length error.

As previously discussed, the dominant sources of non-combinatorial backgrounds to the process $B_s^0 \rightarrow D_s\ell$ are all cases in which the $D_s$ and lepton both result from $B^+$ or $B^0$ decay, either directly or in a subsequent decay. The likelihood function to describe these sources of background is therefore taken to have the same form as the $B_s^0$ signal, except that the lifetime for this sample is fixed to 1.6 ps, which is consistent with the measured average $B$ hadron lifetime [21] and the lifetimes of the $B^+$ and $B^0$ hadrons [20]. The level of this background is a fixed fraction of the signal, as determined in the previous section. The effects of the uncertainty in this fraction on the lifetime are addressed as a systematic error.

The fit must also account for the combinatorial background present in the $D_s\ell$ sample. The functional form used to parameterize this source of background is composed of a positive and a negative exponential, each convolved with the same boost function and Gaussian resolution function as is the signal. The parameters describing these exponentials, and the fraction of each, are free parameters in the fit. This double-exponential shape is motivated by considerations of event topologies that can lead to negative apparent decay lengths, even before resolution effects are considered.

The background present in the event sample is taken into account by simultaneously fitting for the signal $B_s^0$ decays and background contributions. The expected combinatorial background probability is determined for each candidate using the results of the fit to the $K\pi\pi$ invariant mass spectrum. For the lifetime fit, the 253 events found in the region from 50 MeV/c² below the fitted $D_s$ mass to 200 MeV/c² above it are used (see Fig. 1). This avoids the region where the number of $K\pi\pi$ candidates from $D^-$ decays is significant.

The result of the fit to the decay lengths of the 253 candidates that are within the selected $K\pi\pi$ invariant
mass region gives \( \tau(B_s^0) = 1.55^{+0.22}_{-0.21} \) ps, where the error is statistical only. The decay length distributions are shown in Fig. 2 for those candidates with \( KK\pi \) mass within the \( D_s \) mass region, and for those above this region. These illustrate the quality of the fit in a region with a large fraction of signal events and in another region which is dominated by combinatorial background. The curves in Fig. 2 represent the sum of the decay length probability distributions for each event. The figures indicate that the fitted functional forms provide a good description of the data for both signal and background. It should be noted that the fit is to the unbinned data.

5. Evaluation of systematic errors

The sources of systematic error considered are those due to the level, parameterization and source of the background, the potential bias from the selection and fitting procedure, the boost estimation method, the beam spot determination and possible tracking errors.

To determine the effect of the uncertainty in the level of combinatorial background in the \( D_s^- \ell^+ \) candidates, both the uncertainty in the level of background as determined by the fit to the \( KK\pi \) mass spectrum and the statistical variation of the background under the \( D_s \) peak have been considered. This is done by repeating the fit to the \( KK\pi \) invariant mass spectrum with the background fraction constrained to be 37% and 49% and using the resulting event-by-event background probabilities in the lifetime fit. This yields a variation in the \( B_s^0 \) lifetime of \( \pm 0.03 \) ps. The width of the sideband region of the \( KK\pi \) mass spectrum, from which candidates are selected for use in the lifetime fit, has also been varied, resulting in a change in the fitted lifetime value of \( \pm 0.01 \) ps. Several alternative parameterizations have been investigated. For example, terms to allow for a small subset of the candidates in which tracks have been significantly mis-measured and combinatorial background with zero lifetime have been used. In all cases, these additional terms do not significantly improve the quality of the fit. The approach used in our previous publication \cite{41} of having a signal region with a fixed background and a sideband region assumed to have no signal, has also been applied. The difference in the fitted lifetime when this approach is used is less than \( \pm 0.01 \) ps. The effect of the backgrounds involving \( D_s \ell \) that are not from the decay of a \( B_s^0 \) meson, namely from either \( B^+ \) or \( B^0 \) decays, was also considered. The level of this non-combinatorial background was found to be \( (6 \pm 5) \% \). The variation in the level of this background over the given range corresponds to an uncertainty of \( \pm 0.01 \) ps. The lifetime of this background is fixed to 1.6 ps for the nominal result and is varied by \( \pm 0.10 \) ps to account for the uncertainty in this value. This variation results in changes to the \( B_s^0 \) lifetime of \( \pm 0.01 \) ps. Thus we assign a total error due to the background fraction, parameterization and source of \( \pm 0.03 \) ps.

Tests were performed on several samples of simulated data to check for biases in the selection and fitting methods. The results of these tests are consistent with there being no bias: the ratio of the fitted lifetime to the generated lifetime is 1.01 \( \pm 0.02 \). Nonetheless, we correct our determination of the \( B_s^0 \) lifetime by this factor and take the statistical precision of this ratio as a potential selection and fitting bias by assigning a systematic error of \( \pm 0.03 \) ps.

The estimated \( B_s^0 \) energy spectrum that is used by the boost estimation procedure has been varied within the measured limits of the average \( b \) hadron...
energy [22] to yield a variation in the $B_s^0$ lifetime of $\pm 0.02$ ps. The effect of a 6 MeV/$c^2$ uncertainty in the mass of the $B_s^0$ [23] was found to produce a change of less than 0.01 ps in the $D_s^0$ lifetime. A number of alternative methods of boost estimation were used to confirm the method used for the principle result. A method whereby a mean boost is analytically calculated for each event (as used in the previous $B_s^0$ lifetime publication [4]) was also used and the resulting difference of $+0.01$ ps included as a systematic effect. A boost method based on the use of simulated data to estimate the boost was also used and yielded a lifetime less than 0.01 ps from the nominal result. The uncertainty in the measurement of the mass and momentum of the $D_s\ell$ combination that are used to obtain the estimate of the $B_s^0$ energy is found to contribute $\pm 0.01$ ps to the error. Finally, the presence of missing particles, such as the photon when the $B_s^0$ has decayed into a $D_s^*$, changes the fitted lifetime by $< 0.01$ ps. An error of $\pm 0.01$ ps is ascribed to the lifetime due to this source. The total systematic error resulting from the uncertainty in the boost estimation procedure is $\pm 0.03$ ps.

The average intersection point of the LEP beams in OPAL is used as the estimate of the production vertex of the $B_s^0$ candidates. The mean coordinates of the beam spot are known to better than 25 $\mu$m in the $x$ direction and 10 $\mu$m in $y$. The effective r.m.s. spread of the beam is known to a precision of less than 10 $\mu$m in both directions. To test the sensitivity of $\tau(B_s^0)$ to the assumed position and size of the beam spot, the coordinates of the beam spot are shifted by $\pm 25$ $\mu$m, and the spreads changed by $\pm 10$ $\mu$m. The largest observed variation in $\tau(B_s^0)$ is 0.01 ps, which is assigned as a systematic error.

The effects of alignment and calibration uncertainties on the result are not studied directly but are estimated from a detailed study of 3-prong $\tau$ decays [12], where the uncertainty in the decay length due to these effects is found to be less than 1.8% for the data taken during 1990 and 1991 and less than 0.4% for later data. This corresponds to an uncertainty on $\tau(B_s^0)$ of 0.01 ps. The potential for mis-estimation of the decay length error has been addressed by allowing an additional parameter in the lifetime fit which is a scale factor on the measured decay length error. It is found that this parameter is consistent with unity and produces a change in the $B_s^0$ lifetime of less than 0.01 ps.

After applying the correction due to the potential of a bias in the result, and combining the systematic errors in quadrature, we find $\tau(B_s^0) = 1.54^{+0.25}_{-0.21}$ (stat) $\pm 0.06$ (syst) ps. These systematic errors are summarized in Table 1.

### 6. Conclusion

A sample of $B_s^0 \to D_s^- \ell^+\nu(X)$ decays has been reconstructed in which the $D_s$ has decayed into $K^+K^-\pi^-$ through either the $\phi\pi^-$ or $K^0\bar{K}^-$ channels. From 3.6 million hadronic $Z^0$ events recorded by OPAL from 1990 to 1994, a total of 79 $\pm 13$ such candidates are attributed to $B_s^0$ decays. The $B_s^0$ lifetime is found to be

$$\tau(B_s^0) = 1.54^{+0.25}_{-0.21}$$ (stat) $\pm 0.06$ (syst) ps,

where the total fractional error corresponds to about 15%. As predicted by theoretical calculations [3], this result is consistent with the observed value for the $B_s^0$ lifetime [20].

### Acknowledgements

It is a pleasure to thank the SL Division for the efficient operation of the LEP accelerator, the precise information on the absolute energy, and their continuing close cooperation with our experimental group. In addition to the support staff at our own institutions we are pleased to acknowledge the:
