Abstract. Understanding how carbon dioxide (CO$_2$) flux from ecosystems feeds back to climate warming depends in part on our ability to quantify the efficiency with which microorganisms convert organic carbon (C) into either biomass or CO$_2$. Quantifying ecosystem-level respiratory CO$_2$ losses often also requires assumptions about stable C isotope fractionations associated with the microbial transformation of organic substrates. However, the diversity of organic substrates’ $\delta^{13}$C and the challenges of measuring microbial C use efficiency (CUE) in their natural environment fundamentally limit our ability to project ecosystem C budgets in a warming climate. Here, we quantify the effect of temperature on C fluxes during metabolic transformations of cellobiose, a common microbial substrate, by a cosmopolitan microorganism growing at a constant rate. Biomass C specific respiration rate increased by 250% between 13 and 26.5°C, decreasing CUE from 77 to 56%. Biomass C specific respiration rate was positively correlated with an increase in respiratory $^{13}$C discrimination from 4.4 to 6.7 ‰ across the same temperature range. This first demonstration of a direct link between temperature, microbial CUE, and associated isotope fluxes provides a critical step towards understanding $\delta^{13}$C of respired CO$_2$ at multiple scales, and towards a framework for predicting future ecosystem C fluxes.

1 Introduction

Because Earth’s organic carbon (C) cycle is a key regulator of climate, a central goal of biogeochemistry is to understand biosphere–atmosphere C exchange. Globally, almost all C initially assimilated via photosynthesis is respired back to the atmosphere as CO$_2$ by auto- and heterotrophic organisms (Schimel, 1995; Trumbore, 2006). Though we have a reasonably comprehensive understanding of how environmental conditions influence CO$_2$ uptake by photosynthetic organisms (Schimel, 1995; Trumbore, 2006), the influence of temperature on the physiology of heterotrophic microbes must therefore be well understood to project shifts in the global C balance in a warmer climate.

Existing knowledge of Earth’s terrestrial C balance has been bolstered by the use of stable isotopes. A milestone for progress was when photosynthetic responses to environmental conditions were linked to differences between the stable C isotopic composition ($\delta^{13}$C) of atmospheric CO$_2$ and that of plant products (Farquhar et al., 1982). These differences, caused by C isotope fractionation during CO$_2$ diffu-
sion into leaves and subsequent carboxylation (Park and Epstein, 1961; O’Leary, 1981), impart an isotopic fingerprint on ecosystem C pools and permit inference about C fluxes from $\delta^{13}$C of ecosystem C pools at multiple spatiotemporal scales (Farquhar and Richards, 1984; Pataki et al., 2003; Dijkstra et al., 2004; Barbosa et al., 2010). Recent studies remind us that respiratory C losses also leave an isotopic fingerprint on $\delta^{13}$C values of plant tissues via respiration of substrates with distinct $\delta^{13}$C (Batelli et al., 2009; Brüggemann et al., 2011; Ghashghaie and Badeck, 2014), and via C isotope fractionation during decarboxylation in respiratory pathways (Werner and Gessler, 2011; Werner et al., 2011; Tcherkez et al., 2012). Though not all C isotope fractionations during metabolism are well characterized, $\delta^{13}$C of metabolic reaction substrates and products can vary predictably, caused by kinetic or thermodynamic isotope effects (Rossmann et al., 1991; Gleixner and Schmidt, 1997; Cleland, 2005; Tcherkez et al., 2012). Accounting for isotope effects in plant respiratory C losses improves our ability to quantify the contributions of different pools to CO$_2$ fluxes and thus our predictions of terrestrial ecosystem C budgets under changing environmental conditions. Using $\delta^{13}$C of heterotrophically respired CO$_2$ holds similar promise, but if and how changing environmental conditions influence any fractionation factors for the fluxes associated with the liberation of C from OM is unknown.

Significant uncertainty about the direction and magnitude of C isotope fractionation during microbial C transformations (Bowling et al., 2008; Werth and Kuzyakov, 2010) renders quantifying microbial CO$_2$ fluxes in ecosystems difficult. Difficulties arise because microbes in natural systems can access a diverse array of organic substrates with distinct $\delta^{13}$C signatures (Park and Epstein, 1961; Billings, 2006), the respiration of which influences $\delta^{13}$C of respired CO$_2$. Though we know the growth rate of microbial populations influences C flux into and through biomass (Kayser et al., 2005), it is impossible to directly quantify microbial growth in situ. Furthermore, absence of steady-state conditions over a course of CO$_2$ flux measurements makes the interpretation of temperature effects on the magnitude and the $\delta^{13}$C of ecosystem respiration an even greater challenge (Gammnitzer et al., 2011; Nickerson et al., 2013). Thus, establishing a mechanistic understanding of the links between temperature, microbial respiration rates, and C isotope fractionation during substrate transformations at a fundamental level requires that we characterize these processes as temperature changes in isolation from other factors that influence microbial C transformations.

To assess the influence of temperature on microbial growth and respiration rates, we grew a widely distributed gram-negative, heterotrophic bacterium ($Pseudomonas fluorescens$) in continuous culture bioreactors (chemostats) at 7 temperatures ranging from 13 to 26.5 °C (Fig. 1) at reactor dilution rates of approximately 0.14 h$^{-1}$, which is equivalent to the relative growth rates of the microbial popula-

**Figure 1.** Chemostat system comprised of $P. fluorescens$ growing on cellobiose. Seven independent experiments were conducted, with reactor temperatures of 13, 14.5, 16, 18, 21, 23.5, and 26.5 °C; all other conditions were identical. During continuous flow, dilution rate of the reactor (mean = 0.137 ± 0.01 h$^{-1}$ across all experiments) equals microbial growth rate. A peristaltic pump supplied fresh nutrient medium from a reservoir tank to the reactor and removed reactor medium (including biomass) at a constant rate. Headspace volume was flushed with CO$_2$-free air, bubbling through reactor medium and supplying microorganisms with O$_2$. A $^{13}$CO$_2$/$^{12}$CO$_2$ analyzer continuously sampled reactor headspace and measured the concentration and $\delta^{13}$C of respired CO$_2$. 

Significant uncertainty about the direction and magnitude of C isotope fractionation during microbial C transformations (Bowling et al., 2008; Werth and Kuzyakov, 2010) renders quantifying microbial CO$_2$ fluxes in ecosystems difficult. Difficulties arise because microbes in natural systems can access a diverse array of organic substrates with distinct $\delta^{13}$C signatures (Park and Epstein, 1961; Billings, 2006), the respiration of which influences $\delta^{13}$C of respired CO$_2$. Though we know the growth rate of microbial populations influences C flux into and through biomass (Kayser et al., 2005), it is impossible to directly quantify microbial growth in situ. Furthermore, absence of steady-state conditions over a course of CO$_2$ flux measurements makes the interpretation of temperature effects on the magnitude and the $\delta^{13}$C of ecosystem respiration an even greater challenge (Gammnitzer et al., 2011; Nickerson et al., 2013). Thus, establishing a mechanistic understanding of the links between temperature, microbial respiration rates, and C isotope fractionation during substrate transformations at a fundamental level requires that we characterize these processes as temperature changes in isolation from other factors that influence microbial C transformations.

2 Materials and methods

2.1 Pre-cultivation of microorganisms for chemostat inoculation

We pre-cultivated Pseudomonas fluorescens (Carolina Biological Supply, USA) in nutrient solution containing 10 mM NH₄Cl, 1.6 mM KNO₃, 2.6 mM K₂HPO₄, 1.0 mM KH₂PO₄, 0.8 mM MgSO₄, 0.2 mM CaCl₂, 0.1 mM CuCl₂, 0.04 mM FeSO₄, 0.03 mM MnCl₂, and 0.02 mM ZnSO₄, modified from Abraham et al. (1998). The sole C source in the nutrient medium was 10 mM cellobiose (C₁₂H₂₂O₁₁; with a δ¹³C of −24.2 ‰). Cellobiose is a disaccharide consisting of two glucose molecules and a basic module of cellulose. Thus, the C to N to P atomic ratio of the autoclaved, sterile nutrient solution was 100 to 10 to 3.3; its pH was adjusted to 6.5. The bacteria grew for a few days in batch culture in a flask fitted with a vent for air exchange covered by a 0.22 µm filter (Fisher Scientific, USA) to avoid contamination. Vessels contents were stirred continuously in an incubator maintained at 10°C.

2.2 The laboratory mesocosm – the chemostat

The chemostat system was composed of two 1.9 L vessels, a medium reservoir tank and a reactor, each maintained on separate heating/stirring plates (Fig. 1) in separate incubators. The reactor volume was on average 870 mL (see the Supplement, Table S1). The reservoir tank was connected via a flexible tube to the reactor (Tygon E-LFL pump tubing, Masterflex, USA), which in turn had an outlet tube (Fig. 1; both tubes had a 1.6 mm inner diameter). When the chemostat was operated in “continuous culture mode” a peristaltic pump transported fresh medium to the reactor and simultaneously removed medium from the reactor at the same rate. Thus, reactor volume remained constant during all chemostat runs. The 0.22 µm filter in the reservoir tank lid allowed for pressure compensation during withdrawal of nutrient solution in the continuous flow mode. Experimental temperatures were continuously measured with a thermometer (Oakton, USA) placed in the reactor medium (Fig. 1). This thermometer was routinely compared against an internal laboratory standard mercury thermometer, before and at the end of each experiment. The reactor temperatures were adjusted with heating/stirring plate and incubator settings, and kept constant during all experimental runs.

The reactor lid had two ports for gas lines. The outlet port tube was connected to a ¹³CO₂/¹²CO₂ analyzer (G2101-l, Picarro, USA) containing a pump that continuously removed air from the reactor headspace at an average rate of 0.025 L min⁻¹. A water trap (magnesium perchlorate, Costech, USA) was installed between outlet port of the reactor and the gas analyzer. The CO₂ analyzer recorded the concentration and the δ¹³C of the reactor headspace CO₂ at 0.5 Hz. The reactor’s inlet tube was connected to a mass flow controller (MC-50SCCM, Alicat Scientific, USA), which in turn, was connected to a gas cylinder containing CO₂-free air (Fig. 1). The mass flow controller was programmed to maintain the reactor headspace at constant atmospheric pressure; thus, the 0.025 L min⁻¹ headspace air removed by the ¹³CO₂/¹²CO₂ analyzer pump was instantaneously replaced with CO₂-free air flowing from the gas cylinder into the reactor medium. Assuming (1) that 1 mol of O₂ is consumed per 1 mol of CO₂ produced in aerobic respiration, (2) a typical reactor headspace CO₂ concentration of around 2000 ppm at steady state (see Fig. 2a and below), and (3) an O₂ concentration of 21 % in the air supply to the reactor, the air supply permitted continuous aerobic metabolism. Routine tests with CO₂-free air in sterile chemostats were performed to ensure there were no leaks in the system.

2.3 The chemostat run – standardized protocol and description of events

We conducted seven independent chemostat runs, at temperatures of 13, 14.5, 16, 18, 21, 23.5, and 26.5 °C at a dilution rate of, on average, 0.14 h⁻¹, in random temporal order. For each of the chemostat runs, we inoculated the reactor with a 10 mL aliquot of the P. fluorescens pre-culture and activated the flow of CO₂-free air through the reactor; this was considered time 0. At the initial stage of a chemostat run, the bacteria grew in batch culture, that is, there was no flow of

![Figure 2. Example time course of the evolution of reactor headspace CO₂ concentration (a) and δ¹³C of the CO₂ (b) of the chemostat run at 23.5 °C in hours since inoculation of the reactor with pre-cultured P. fluorescens. Data points are hourly means. Error bars (where visible) denote ±1 SD. The reactor was shifted from batch to continuous culture mode 45 h after inoculation. Microbial respiration rate and the δ¹³C of respired CO₂ were measured between 70 and 74 h after inoculation when the culture reached steady state.](www.biogeosciences.net/13/3319/2016/ Biogeosciences, 13, 3319–3329, 2016)
fresh nutrient medium from the reservoir tank to the reactor, and no removal of medium from the reactor (Fig. 1).

2.3.1 Respiration measurements at chemical and isotopic equilibrium in the continuous flow chemostat at steady state

At the initial pH of 6.5, inorganic C in the fresh reactor medium was mainly in the form of H$_2$CO$_3$ (aq) and HCO$_3^-$ (Stumm and Morgan, 1981). By continuously bubbling CO$_2$-free air into the reactor, we expelled these initial inorganic C pools from the reactor medium. This was evident by concentrations of reactor headspace CO$_2$ of virtually zero in the early stages of batch culture after each run’s inoculation (Fig. 2a). During the phase of rising reactor headspace CO$_2$ via respiratory activity of the exponentially growing population (Fig. 2a), inorganic C in the reactor medium was still increasing addition of CO$_2$ from microbial respiration. That is, at any point in time during the phase of increasing reactor headspace CO$_2$ concentration, the nutrient medium acted as a sink for respired CO$_2$ (see also the Supplement).

Once the respiratory activity of the growing microbial population pushed the reactor headspace CO$_2$ concentration above 500 ppm, we transferred the chemostat into the “continuous culture, open system” mode (Figs. 1, 2; Ferenci, 2008; Bull, 2010). The peristaltic pump henceforth transported fresh nutrient medium from the reservoir tank to the reactor at a constant rate of, on average, 118 mL h$^{-1}$ (Table S1), and simultaneously removed medium from the reactor at the same rate so that the reactor volume remained constant. Initial chemostat experiments indicated that when headspace CO$_2$ concentrations reached 500 ppm, the bacterial population was sufficiently dense to maintain itself without being washed out via dilution. Depending on the reactor temperature, the onset of the continuous culture mode occurred between 40 h (at 26.5°C) and 72 h (at 13°C) after inoculation.

After the switch from batch to continuous culture, the rate of increase in reactor headspace CO$_2$ concentration gradually slowed because cells were continuously diluted into the waste stream (Fig. 1), and approached a phase where the CO$_2$ concentration became stable (Fig. 2a). At this point, bacteria grown in continuous culture had reached the phase of steady-state growth and physiology (see Ferenci, 2008; Bull, 2010). A key feature of the continuous culture chemostat relevant to our study is that at this steady state, the constant dilution rate of the reactor (the medium flow rate divided by the reactor volume) was equivalent to the specific growth rate of the microbial culture (Bull, 2010). That is, washout of cells with the nutrient medium flow is balanced by cell division so that the size of the population in the reactor can be expected to be reasonably constant in the time frames employed here (see discussion in Ferenci, 2008; Bull, 2010).

Critically, when reactor headspace CO$_2$ concentrations approached the steady state, inorganic C pools came to their respective equilibria as well (Stumm and Morgan, 1981). At this point, pools of H$_2$CO$_3$ (aq) and HCO$_3^-$ were no longer a net sink for respired CO$_2$. As reactor headspace CO$_2$ concentrations reached steady state, the system supported constant microbial CO$_2$ production reflective of steady-state growth under constant environmental conditions, and reflected chemical equilibrium (i.e., constant size) of the dissolved inorganic C pools. Thus, the rate of CO$_2$ addition to the reactor headspace volume at steady state accurately represented the CO$_2$ released during microbial respiration (see also the Supplement).

We calculated the molar CO$_2$ production rate of the microbial population as the product of the average molar CO$_2$ concentration measured by the $^{13}$CO$_2$/$^{12}$CO$_2$ analyzer for 5 h at steady state (Fig. 2a) multiplied by the molar air flow rate through the reactor, which was calculated as

$$\text{air flow (mol min}^{-1}) = 0.96 \text{ atm} \cdot 0.025 \text{ L min}^{-1} / (0.082 \text{ atm L mol}^{-1} \text{ K}^{-1} \cdot 296 \text{ K}),$$

with 0.96 atm and 296 K being the barometric pressure and the temperature in the lab where the experiments were performed, 0.025 L min$^{-1}$ the average volumetric headspace flow rate through the reactor and 0.082 atm L mol$^{-1}$ K$^{-1}$ the gas constant.

The $\delta^{13}$C of the reactor headspace CO$_2$ during the earliest batch culture phase was generally very negative; the $^{13}$CO$_2$/$^{12}$CO$_2$ analyzer cannot accurately measure $^{13}$C and $^{12}$C in very low CO$_2$ concentrations (Fig. 2b). The $\delta^{13}$C of reactor headspace CO$_2$ became less negative as the CO$_2$ concentration increased (Fig. 2b). During the “climbing” phase of the reactor headspace CO$_2$, the $\delta^{13}$C of the CO$_2$ pool was influenced by isotopic fractionation among gaseous CO$_2$, H$_2$CO$_3$ (aq) and HCO$_3^-$ (Vogel et al., 1970; Mook et al., 1974; Stumm and Morgan, 1981; Szaran, 1997), because the dissolved inorganic C pools functioned as a net sink for respired CO$_2$. At steady state, with constant headspace CO$_2$ concentrations and constant size of the dissolved inorganic C pools (see above), isotopic equilibrium was achieved, evidenced by constant $\delta^{13}$C readings of reactor headspace CO$_2$ (Fig. 2b). As such, in this open system at steady state, the $\delta^{13}$C of the CO$_2$ leaving the reactor (the CO$_2$ measured by the analyzer) is identical to the $\delta^{13}$C of microbial respiration (Craig and Gordon, 1965; Fry, 2006). Importantly, this principle is valid irrespective of temperature, microbial growth rate, or microbial biomass in the reactor. (See the Supplement for an elaboration of the principle of chemical and isotopic equilibrium.)

We used the average $\delta^{13}$C measurement of reactor headspace CO$_2$ over the same 5 h in the stable phase employed for calculations of microbial respiration rates (see above) as the isotopic signature of CO$_2$ respired by the microbial culture at each temperature. Any measurements of
headspace CO$_2$ and $\delta^{13}$C during the climbing phase before steady state (Fig. 2) were not used in these calculations.

For the example chemostat at 23.5 °C, the half-life of the reactor ($t_{1/2}$), i.e., the time it took until 50% of the reactor medium was exchanged with fresh tank medium, was 5.2 h (with $t_{1/2} = \ln(2)/(\text{medium flow rate/reactor volume})$; Table S1). In a homogeneous, well-mixed system such as that employed here, 95% of the pool (i.e., the reactor) is exchanged with new medium within approximately 5 times the half-life. Thus, during the respiration measurements between time 70 and 74 h (in the example time course in Fig. 2), any “leftovers” from the batch culture mode were insignificant, and the microbial culture could be considered homogeneous. This principle was applicable to all chemostat runs we performed.

After the 5 h respiration measurements were completed, we disconnected the gas lines from the reactor, connected the mass flow controller directly to the $^{13}$CO$_2$/$^{12}$CO$_2$ analyzer, and replaced the CO$_2$-free air cylinder with a reference gas cylinder containing 1015 ppm CO$_2$ at a $\delta^{13}$C of $-48.9$‰ (Matheson, USA). This laboratory gas was previously calibrated against secondary CO$_2$ standards (Oztech, USA) and served for any necessary corrections of the $\delta^{13}$C of the reactor headspace CO$_2$ measurements. Across the seven standard measurement procedures after each individual chemostat run, the $\delta^{13}$C measured for the laboratory standard gas showed only slight variation (1 SD = 0.16‰). CO$_2$ concentration measurements needed no correction; measurements of lab-internal gases with previously determined CO$_2$ concentrations between chemostat runs showed very stable and accurate analyzer performance.

### 2.3.2 Measurements of extracellular enzyme activities at steady state

Using principles detailed by Lehmeier et al. (2013) and Min et al. (2014), we tested reactor medium for activity of the extracellular enzymes β-glucosidase and β-N-acetyl glucosaminidase across all chemostat temperatures; we never detected extracellular activity of either enzyme. The lack of extracellular β-glucosidase activity indicates that the sole C source, cellulose, was directly taken up by microbes and cleaved intracellularly into glucose monomers for further metabolism. The lack of extracellular β-N-acetyl glucosaminidase activity suggests that the inorganic N provided in nutrient medium was the sole source of N taken up by _P. fluorescens_. These findings do not rule out the possibility that _P. fluorescens_ may have taken up (i.e., recycled) any exuded C-based metabolic compounds, although such a scenario in continuous culture conditions may not appear to be energetically favorable. Thus, the assumption that the sole resources used by _P. fluorescens_ were the cellulose and the nutrient medium appears reasonable.

### 2.3.3 Harvest of microbial biomass at steady state

Immediately after completing the 5 h respiration measurements, we filtered approximately 300 mL of reactor medium for steady-state microbial biomass using 0.2 µm filters made of polyethersulfone (Pall, USA) and a vacuum pump. The filters had previously been oven dried for 48 h at 75 °C and their dry weight determined. We then oven dried the filters post filtration for 48 h at 75 °C, removed some of the dry biomass and weighed 1.2 mg of the material into tin cups for subsequent combustion in an elemental analyzer (1110 CHN Combustion Analyzer, Carlo Erba Strumentazione, Italy) coupled to a ThermoFinnigan DeltaPlus mass spectrometer (Finnigan MAT, Germany) at the Keck Paleoenvironmental and Environmental Stable Isotope Laboratory (The University of Kansas, USA). We thus determined biomass C (and N) elemental content, as well as the $\delta^{13}$C of the biomass. In this analysis, the samples were compared against a laboratory standard CO$_2$ previously calibrated against the same secondary CO$_2$ standards as used in calibration of the CO$_2$ standard used for respiration measurements (see above). The $\delta^{13}$C of the substrate cellulose was measured likewise. Dry weight of the sampled reactor aliquots and the C content obtained from elemental analysis served to calculate total microbial C content in the steady-state reactor and to calculate specific respiration rates.

At all temperatures studied, biomass C and N contents were virtually the same, on average 27% and 8% of microbial dry mass, respectively (Table S1). From mass balance calculations, we determined that only a small percentage of the C and N supplied via fresh medium from the tank was taken up to fuel microbial growth (2.8 and 4.3% on average for C and N, respectively). This suggests that the observed temperature effects on specific respiration rates and CUE were not confounded by any differences in C and N limitations at the different temperatures (Goldman and Dennet, 2000; Cotner et al., 2006; Chrzanowski and Grover, 2008).

### 3 Results and Discussion

For _P. fluorescens_ grown in continuous culture, CUE, defined as SGR/(SGR + SRR), declined with increasing temperature, from 77% at 13 °C to 56% at 26.5 °C (Fig. 3a). Because specific growth rates were similar across the experimental temperatures (137 mg g$^{-1}$ h$^{-1}$, ±8 (1 SD); or 13.7 % h$^{-1}$ in relative terms; Fig. 3b), the decline in CUE was due to the 2.5-fold increase of SRR with temperature, which rose from 45 mg g$^{-1}$ h$^{-1}$ at 13 °C to 113 mg g$^{-1}$ h$^{-1}$ at 26.5 °C (Fig. 3b). The decline in CUE is also evident in the more than 50% reduction in steady-state dry microbial biomass with increasing temperature (Fig. 3a). For example, though SGR was approximately the same and thus the fraction of biomass replaced per time similar across all experimental temperatures (0.147 and 0.141 at 13 °C and 26.5 °C, respectively;
Fig. 3b), microbes at 13 °C generated 20.9 mg biomass h⁻¹ while those at 26.5 °C generated less than half the amount (9.5 mg biomass h⁻¹).

Because we did not quantify possible C losses from the population at steady state such as secretion of organic acids or other compounds (El-Mansi and Holms, 1989; Nanchen et al., 2006), gross rates of steady-state cellobiose C uptake may have been slightly higher than what was calculated from the sum of SGR and SRR. However, the direct observation of P. fluorescens’ CUE is consistent with the negative effect of increasing temperature on microbial CUE widely reported in literature for soils and aquatic ecosystems (del Giorgio and Cole, 1998; Gillooly et al., 2001; Rivkin and Legendre, 2001; Apple et al., 2006; Manzoni et al., 2012; Frey et al., 2013; Tucker et al., 2013).

Across the chemostat runs, we observed strong C isotope fractionations, which created pronounced differences in δ¹³C between microbial biomass and the sole C substrate, cellobiose, and between microbial biomass and respired CO₂ (Fig. 4). Microbial biomass exhibited 5.5–10.5 ‰ more negative δ¹³C values than the cellobiose and respired CO₂ was even more ¹³C depleted, at least 4.4 ‰ more negative than the biomass (Fig. 4a). Because each chemostat was at steady state, isotopic mass balance dictates that ¹³C “missing” from cellobiose had to accumulate in another pool in the reactor. The only pool that could have been enriched with the “missing” ¹³C was reactor DOC, which we analyzed for δ¹³C in four out of the seven chemostat runs (Fig. 4a). Reactor DOC consisted of a large pool of cellobiose (because the rate of C consumption by the chemostat cultures was, on average, only 2.8 % of the rate of C supply) and presumably a pool of additional organic compounds (e.g., acetate). Such compounds appear to be typically secreted from microbial cells at low rates in aerobic chemostats operated at dilution rates similar to those of our runs (El-Mansi and Holms, 1989; Nanchen et al., 2006), and have been shown to be enriched in ¹³C compared to cellular biomass (Blair et al., 1985). However, because such a small fraction of the available cellobiose was taken up by P. fluorescens, the fraction of total DOC comprised of secreted organic compounds was small. As a result, ¹³C enrichment of any microbial exudates was insufficient to enrich bulk DOC to an extent detectable by the isotope ratio mass spectrometer (Fig. 4a).

The majority of the fractionation between P. fluorescens biomass and the substrate was most likely due to discrimination against ¹³C during cellobiose uptake. If we assume that P. fluorescens secreted organic compounds at a rate of 10 % of the sum of SGR and SRR (El-Mansi and Holms, 1989) and that the bacteria did not discriminate against ¹³C-containing cellobiose during uptake (and thus assimilated cellobiose possessed a δ¹³C of −24.2 ‰), isotopic mass balance dictates that the δ¹³C of the C secretion flux (Fig. 5) would have to be +70 ‰, at minimum, across all temperatures. To our knowledge, such high metabolic discrimination against ¹³C would be very unusual for biological systems (O’Leary, 1981). An alternative and more likely scenario is therefore that P. fluorescens took up less ¹³C-containing cellobiose than was supplied as substrate, and that discrimination during uptake contributed substantially to P. fluorescens biomass and respired CO₂ being more ¹³C depleted than the cellobiose supplied. This conclusion holds for all temperatures studied. If we assume for the example 23.5 °C chemostat run at steady state (Figs. 2, 5) that P. fluorescens secreted organic compounds at a rate of 10 % of the sum of SGR and SRR, and we further assume that the δ¹³C of secreted compounds was 11.7 ‰ less negative than that of the biomass (Blair et al., 1985), that is −18.1 ‰, then the δ¹³C of the cellobiose taken up would have been −31.1 ‰, which is only a 7 ‰ difference from the cellobiose provided, and therefore probably a more likely scenario (Fig. 5).

Substantial ¹³C depletion of respired CO₂ relative to microbial biomass has not, to our knowledge, been reported in other studies. With the microbial C consumption rate amounting to only 2.8 % of the rate of C supply, C availability was high compared to what microbes in their natural environments typically experience (Tempest and Neijssel, 1978; Cole et al., 1988; Hobbie and Hobbie, 2013), potentially promoting enzymatic discrimination. The cellobiose δ¹³C of −24.2 ‰ implies a ¹³C / ¹²C ratio of ∼ 1.91. Considering the molecular formula of cellobiose C₁₂H₂₂O₁₁, this means that not more than about one out of eight cellobiose molecules in the supplied substrate included a ¹³C atom. Faster diffusion of the isotopically lighter cellobiose molecules may have contributed to a lower probability of ¹³C-containing cellobiose approaching bacterial membrane uptake sites, and hence, to the differences between δ¹³C of substrate and biomass (Fig. 4a). However, isotope fractionation during diffusion – a physical process dependent on compound mass – would likely exhibit a continuous temperature response. Thus, it seems unlikely that fractionation during diffusion was the primary driver of the pronounced, discontinuous changes in the difference between substrate and biomass δ¹³C, which ranged from 5.5 to 10.5 ‰ (Fig. 4a). Rather, this variation, with one apparently linear part between 13 and 16 °C and another between 18 and 23.5 °C, may be explained parsimoniously by a significant, discontinuous reorganization of enzyme-mediated C fluxes into and out of bacterial cells (see Nanchen et al., 2006), induced by differences in temperature at which P. fluorescens was growing and the related differences in substrate uptake rates.

Evidence from work on C isotope distribution within carbohydrate molecules (e.g., Rossmann et al., 1991; Gleixner and Schmidt, 1997) suggests non-random distribution of ¹³C in biological molecules (such as cellobiose). Based on such phenomena, it is probable that the ¹³C atom in ¹³C-containing cellobiose was consistently at the same position within the molecule, which rules out the possibility that any changes in the intramolecular ¹³C distribution of cellobiose were responsible for the observed δ¹³C patterns in biomass and respired CO₂ (Fig. 4). Hence, the discontinuous pattern
of δ\textsuperscript{13}C of respired CO\textsubscript{2} with temperature, similar to the pattern for δ\textsuperscript{13}C of the biomass (Fig. 4a), presumably reflects the downstream consequence of an upstream change in δ\textsuperscript{13}C of the metabolic substrate taken up and ultimately respired. However, the more negative δ\textsuperscript{13}C of respired CO\textsubscript{2} compared to that of biomass is, to our knowledge, the most direct evidence to date for \textsuperscript{13}C discrimination during respiration of a heterotrophic microbe. The observation of a substantial respiratory \textsuperscript{13}C discrimination corroborates findings drawn in earlier studies (Šantrůčková et al., 2000; Fernández and Cadisch, 2003) and is also consistent with plant studies reporting C isotope discrimination during dark respiration in roots (Klumpp et al., 2005; Batellier et al., 2009; Ghashghaie and Badeck, 2014). Our observations of respiratory discrimination against \textsuperscript{13}C highlight the similarity of heterotrophic, aerobic respiratory pathways, and isotope effects within them, across life’s domains.

In contrast to the discontinuous relationship between biomass δ\textsuperscript{13}C and temperature, we observed a comparably continuous and linear increase in respiratory discrimination against \textsuperscript{13}C with temperature (Fig. 4b). This increase generated a marginally positive significant (P = 0.08) correlation with SRR (Fig. 6), and hence a marginally significant (P = 0.07) correlation with CUE. A physiological interpretation of this finding is not straightforward, as multiple, possibly simultaneous enzymatic fractionations may have con-
Figure 5. Schematic of an individual P. fluorescens cell, representing the sample population growing at 23.5 °C with one available substrate at a constant relative growth rate of 0.14 h⁻¹ at steady state (Fig. 2), with measured (solid boxes) and estimated (dashed boxes) magnitudes of C and ¹³C fluxes into and out of the population. Designated fluxes include specific uptake rate of cellobiose (F_{SUR}), specific growth rate (F_{SGR}), specific respiration rate (F_{SRR}), and specific excretion rate (F_{SER}), in relation to steady-state biomass C in the chemostat, where F_{SUR} = F_{SGR} + F_{SRR} + F_{SER}. The estimate of δ¹³C uptake is based on the assumption that δ¹³C exuded C is 11.7 ‰ less negative than δ¹³C biomass (Blair et al., 1985) and that F_{SER} is 10% of the sum of F_{SGR} and F_{SRR} (El-Mansi and Holms, 1989). In contrast to this experimental system, in natural environments measurements of boxed pools and fluxes can be confounded by the presence of dormant microorganisms, unknown microbial growth rates, diverse available substrates, and a lack of steady-state CO₂ fluxes.

Figure 6. Correlation between the specific respiration rate (in mg C per g microbial biomass C and hour) of P. fluorescens growing in continuous chemostat culture at temperatures ranging from 13 to 26.5 °C and the carbon isotope discrimination during respiration. The dashed line denotes a linear regression of the form y = 0.03x + 3.6; \( R^2 = 0.48 \); \( P = 0.08 \).

Contributed to the observed δ¹³C of respired CO₂ (Dijkstra et al., 2011; Tcherkez et al., 2012). It could simply result from a proportionally increasing flux through respiratory pathways, with associated stronger expression of ¹³C discrimination by the enzymes involved (Tcherkez et al., 2012), or could result from increasing temperatures altering the relative fluxes through respiratory pathways (Chung et al., 1976; Wittmann et al., 2007; Dijkstra et al., 2011) such that the overall observed respiratory ¹³C discrimination increased with temperature. This may be possible given that respiratory pathways can exhibit distinct fractionation factors (Bathellier et al., 2009 and references therein) and prompt different, specific C atoms to undergo decarboxylation from the two glucose units of the substrate cellobiose, which contain non-randomly distributed ¹³C atoms (Rossmann et al., 1991; Gleixner and Schmidt, 1997). If relative fluxes through different respiratory pathways changed with temperature, the continuous nature of the relationship between temperature and respiratory ¹³C discrimination suggests a smooth transition compared to the abrupt and discontinuous shifts in apparent uptake and/or secretion discrimination described above. Future metabolic flux analyses linked to isotopic approaches sensitive enough to quantify C isotopes in microbial exudation will be well suited to explore how C allocation to distinct, aerobic respiratory pathways may vary with temperature and result in varying δ¹³C of respired CO₂.

4 Conclusions

Our observations clearly show a decline in microbial CUE with increasing temperature when C substrate is plentiful and demonstrate the mechanism driving it – an increase in SRR. The relationship between CUE and temperature underscores the importance of incorporating variable, temperature dependent SRR, which influences CUE and growth efficiency, in ecosystem process models. The temperature-driven changes in SRR and respiratory discrimination against ¹³C were not independent of each other, suggesting that increasing SRR, to some degree, drives enhanced C isotopic discrimination. We demonstrate that C isotope discrimination associated with microbial decomposition of OM can impart large and variable isotopic signatures on C pools typically characterized...
and interpreted in biogeochemical studies at any scale. Further exploration of the drivers of C isotope fractionations during microbial OM transformations could exploit an experimental approach similar to that presented here to investigate the roles of resource stoichiometry, identity of the organism or the supplied substrate, or competition among microbial populations. To date, efforts to partition flux components of net ecosystem exchange have assumed little to no fractionation between respired substrates and the resultant CO₂. Our results suggest that this assumption must be reevaluated, and represent a first step towards an isotopically explicit, mechanistic framework for microbial C isotope fluxes in Earth systems.

Data availability

The data presented in this study are available for collaborative use by anyone interested; contact the corresponding author for access to the data.

The Supplement related to this article is available online at doi:10.5194/bg-13-3319-2016-supplement.

Author contributions. Christoph A. Lehmeier and Kyungjin Min performed the experiments; all authors contributed to all other parts and stages of the manuscript.

Acknowledgements. We thank Susan Ziegler, Jarad Mellard, and Chao Song for helpful discussions during the design of the experiments; Greg Caine for expert stable isotope analysis and the provision of isotopic standards, Susan Ziegler, Mike Burrell, Karl Auerswald, Hanns-Ludwig Schmidt and John Kelly for comments on the manuscript; Gil Ortiz with assistance generating Fig. 5; the anonymous referees for their time and constructive comments; and the National Science Foundation of the USA for funding (grant no. DEB-0950095 and EAR-1331846).
