#### Abstract

This thesis investigates the effectiveness of using the Contract Net Protocol, an auction type system, for controlling task allocation among a group of robots, and presents and evaluates a strategy of using Artificial Neural Networks to formulate adaptive bids within the framework of the Contract Net Protocol. The robots were used in a foraging environment and showed that excellent communication among robots leads to a need for a social control mechanism for managing the robots, such as the Contract Net Protocol. The experiments also confirmed that a moderate benefit can be gained by using adaptive bidding within the framework of the Contract Net Protocol.

## Acknowledgements

I would like to thank my parents, Robert and Terry Kensler for having the wisdom and foresight to provide me with my own computer far before it became so common for individuals, much less small children, to have their own computer.

I must also give thanks to my elder brother, Andrew Kensler, who has been my lifelong programming mentor.

My wife Jennifer is to be thanked for putting up with me and for helping with the statistics in this project.

Dr. Nancy Kinnersley also has my gratitude for providing me with the opportunity to be a Graduate Teaching Assistant, which has been a learning experience in and of itself, and has also provided me with this opportunity to pursue my studies.

Finally, I must give much thanks to Dr. Arvin Agah for putting up with one fiercely and perhaps foolishly independent graduate student.

## 1. Introduction

## A. Motivation

Imagine she is new to the US and is going to do some traveling by car. She is planning on traveling first from Kansas City, Kansas to Chicago, Illinois. Later, she is to travel from Omaha, Nebraska to Cleveland, Ohio. Then from Minneapolis, Minnesota to Kansas City, Kansas. Finally, she is to travel from Kansas City to Chicago again.

At first, one does not know anything about US roads, so she finds a map and determines the most direct roads to get from Kansas City to Chicago and travel this path. She finds that the roads involved are small roads with low speed limits.

Next, she travels from Omaha, Nebraska to Cleveland, Ohio via a major highway, and finds that the roads have a number of lanes and also have a higher speed limit than the roads from Kansas City to Chicago. This includes a section of highway between Chicago and Des Moines, Iowa. On the next trip, she again takes a major highway between Minneapolis and Kansas City, including a section between Des Moines, Iowa and Kansas City.

The next trip involves once again going from Kansas City to Chicago. The question now arises as to what path she is going to take. Is one going to take the most direct path, which because of the nature of the roads will take 20 hours to get from Kansas City to Chicago, or take a less direct path, via major highways and get to Chicago in 12 hours?

For truck drivers who base their livelihood on driving, such decisions can be extremely important. While getting to Chicago quicker would be nice, it requires driving a longer distance and at much higher speeds, resulting in increased gas consumption. Thus a truck driver must make a decision based upon her own learned experience as to whether increased speed at the cost of increased gas consumption, or lower gas consumption at the cost of speed, is ultimately going to be more profitable.

This evaluation based upon learning is then going to form the basis of how much the truck driver is going to charge for her work. Additionally, even if two trucks take the same path, there may be other considerations, such as how much can each truck carry at a time? One truck may be able to only carry two thirds of what needs to be moved, thus requiring two trips, while the other truck may be able to carry it all in one trip.

Given this, it is not expected that every truck should charge the same amount for accomplishing a task (moving something), because the trucks have different capabilities. The variation on pricing then essentially acts as a function of the efficiency of using a particular truck. The system as a whole then, benefits; and an individual with a job for a trucker chooses the trucker who offers to do it for the least amount of money, as that trucker is likely going to be the most efficient.

Getting quotes from multiple truckers for the cost of a job then becomes an important part of keeping the system working efficiently. This also results in a de facto auction.

In this thesis we examine whether the concept of informed bidding improving overall system efficiency can be carried over to a multi-agent robotic environment.

Although the cost of robotics is currently quite high, it is likely that the cost will decline and give rise to more widespread use of multi-robot systems. These systems will need to be coordinated. Task distribution through an auction type system with adaptive bidding is a promising form of coordination as it mirrors human situations such as truck drivers moving items across the country.

## B. Approach

In this research, artificial neural networks are used for path planning to create informed bids for use in a contract net (auction) system for the foraging problem.

Path planning in this case involves deciding on a path to and from foraging locations and a location at which foraged items may be gathered. This involves deciding whether or not to go through areas of harsh terrain that can slow down a robot and possibly damage it.

A foraging problem was used for the experiments because it is a problem concerned with how individual behaviors affect overall system efficiency with sources of inefficiencies being the result of environmental factors, and not hostile agents actively trying to cause inefficiencies.

Within the foraging problem, there are multiple tasks to be accomplished, in the form of multiple food sources that may be gathered from. In this experiment, we examine the use of the Contract Net Protocol [1], which is a task distribution system based on auction, with adaptive bidding.

The Contract Net Protocol has previously been successfully used in a robotic multi-agent system [11] and for path planning [12], but the importance of the formation and adaptation of the bids to the overall system efficiency has not been examined, which is the focus of this thesis. For this reason, an environment devoid of hostile agents was desired, so as to simply show the importance of adaptive bidding, although examination of an adaptive bidding system in an environment with hostile agents would likely prove interesting future work.

An artificial neural network was used to adaptively create bids. Artificial neural networks have previously been used for path finding purposes [13], but in this thesis, numerous such networks are used not only for path finding, but are also used as the basis of a bidding process.

## C. Thesis structure

This thesis is organized into five sections. The first section details the motivation, with a real life analogy and introduces the problem, followed by a brief description of the approach taken for the experiment in this thesis. The second section describes background and related work in depth that forms the foundation of the experiment
conducted in this thesis. The third section describes the methodology of the experiment. The results of the experiments are presented and discussed in the fourth section; the conclusion and final remarks are in the fifth section.

## 2. Background and Related Work

## A. Artificial Intelligence

Artificial Intelligence is a well known name for a rather nebulous field of study, that is in fact a collection of fields. There are four different main views of what Artificial Intelligence is (as defined by Russell and Norvig [14]): "systems that think like humans", "systems that think rationally", "systems that act like humans", and "systems that act rationally". Part of the nebulosity of the definition of the field arises from it having borrowed elements from a number of fields such as philosophy, mathematics, economics, neuroscience, psychology, linguistics, and anthropology.

There are numerous subfields in artificial intelligence such as knowledge-based systems, neural networks, multi-agent systems, natural language processing, automated reasoning, machine learning, robotics, planning, game playing, etc.

At its most general definition artificial intelligence is about creating "intelligent entities" [14] or taking entities and making them more "intelligent".

## B. Distributed Artificial Intelligence and Multi-Agent Systems

Within the field of artificial intelligence, one may be concerned with making a single entity intelligent, or may be concerned with making multiple entities intelligent. The study of how to make multiple entities intelligent comprises a major sub-field in artificial intelligence: distributed artificial intelligence. Distributed artificial intelligence can be defined rather generally as "the subfield of artificial intelligence (AI) concerned with concurrency in AI computations, at many levels" $[16]$ or more specifically in relation to multi-agent systems as "the study, construction, and application of multi-agent systems, that is systems in which several interacting, intelligent agents pursue some set of goals or perform some set of tasks" [15]. These agents may be heterogeneous or homogenous, they may also be cooperative or competitive [17].

In the experiment investigated in this thesis, multiple types of robots are used, but used separately in a homogenous fashion. The robots were both cooperative and competitive, in that they were individually competitive, but collectively this competitive nature resulted in cooperation to increase the efficiency of the system as a whole.

## C. Contract Net Protocol

The idea of using an auction system for task distribution in multi-agent systems (MAS) has been around for a number of years. One prominent auction system proposed for task distribution in MAS is the Contract Net Protocol proposed by RG Smith in 1980 [1].

In this protocol, an agent finds a task to be completed (how this is done is not described). This agent then acts as a manager for the task if it cannot or will not complete the task by itself. The manager may also decompose the task if possible, feasible, and required. This manager sends out a call for bids to other agents, and these agents bid on the task, or the decomposed sub-tasks. The manager selects the best agent for the job based on some criteria. This basic concept has been used in a variety of approaches, including in systems with multiple unmanned aerial vehicles (UAVs) [2].

## D. Selection of Auction House Type

There are a number of different auction systems to consider. Four main types [3] are:
1.The English auction system, which is a first-price, open-cry system where each bidder may raise their bid at any point during the auction so long as the new bid is higher than all other bids already placed by competing bidders. All bids are public.
2. The First-Price, Sealed Bid auction system, in which a bidder submits a sealed bid to an auctioneer without knowing how other bidders have bid.
3. The Dutch auction, in which an auctioneer starts a bid at a high price and gradually lowers the price until someone is willing to pay for it.
4. The Vickrey auction, in which each bidder submits a sealed bid to the auctioneer. The highest bidder wins, but pays the amount bid by the second highest bid (although a variation of this method as used for selling multiple items is also sometimes called a Dutch auction [4]).

The traditional Contract Net Protocol uses a version of First-Price, Sealed Bid auction, in which only the winning bidders are notified of the auction's termination. The reason cited for this is that informing losing bidders that they have lost the auction will drastically increase the amount of communications [1], which will have a detrimental effect on the system as a whole. If another system, such as the English auction system was instead used, the amount of message traffic would significantly increase.

In the area of robotics, the volume of inter-agent communications has generally been a limiting factor, especially in ad-hoc systems that 'broadcast' messages because broadcasts are actually emulated, not built directly in [5]. In this thesis, we are examining a system that may not be fully feasible at the present time. One such potential assumption made is that the volume of communications that are permissible will increase in the future to such a point that using any auction system, regardless of the volume of communication required, will be feasible. Given this assumption, we must examine different types of auctions and see whether one or more types of auctions would work better in a system of competitive contractors.

In the English auction system, bids are made public, which reveals the bidding strategies of competitors. In the case of contractors, using an English auction system would allow each bidding contractor to know for how much competing contractors believe they can do a job.

This can potentially be useful for giving a contractor who does not have a good idea of how much a job will cost some initial idea of the cost of the job (assuming other contractors have a better idea of how much the job will likely cost). While there is certainly some potential for increasing the efficiency of the system as a whole by allowing this kind of inferred knowledge transfer through the bidding process, this is not within the focus of this thesis. In this work we want to use an agent's learning from its own experiences as the basis of the formulation of its bid.

The only remaining potential benefit of the English auction system is that a bidder may win an auction for less than what they were willing to spend. In the case of this thesis however, the bids are only important for establishing which contractor believes it can do the specified job with the least energy, the exact quantification of the bid is irrelevant.

Thus using the English auction system provides no special benefit for this work. However, a possible extension of this project would be to use the English auction system. and have a contractor take into consideration how much other contractors have bid. Although there is an assumption that the robots in our system will be able to handle the volume of communications needed for any type of auction, we are still left with the English auction system providing no benefit, but requiring additional amounts of communication compared to other types of auctions.

The next type of auction to consider is the First Price, Sealed Bid auction. In this type of auction, the bids are not made public. As it has already been described, in the current context of this project, bids do not need to be made public as bidders are learning from their own experiences in completing work, rather than learning from the bidding process. In this system, each bidder makes an individual estimate of how much energy will be required to complete a task. Each bidder makes only one bid, thus the volume of communications required for this type of auction is held to a minimum. The robot that believes that it can do the task using the least amount of energy will be given the task. As with the English system, this type of auction provides no special benefit in the context of this project, but it requires less communication than the English auction.

The Dutch auction involves an auctioneer gradually lowering a price (or in the case of contractors, increasing the energy believed to be needed) until the price is low enough that a bidder bids and wins the auction. This type of auction is semi-public in that the winning bid is known, but other non-winning bidders' estimation of the cost of the item is not known. This will not provide as much inferred knowledge as the English auction; although, it will likely need less communication than the English system. Therefore there are no special benefits from using this type of auction in the context of this project. It requires less communication than the English system, but will require more communication than the First Price, Sealed Bid Auction.

The last type of auction is the Vickrey auction, which is a Dutch auction where the winning bidder wins the auction, but for the amount that the second highest bidder bid. As was mentioned earlier, we are not concerned with the exact bidding amount, but are
simply concerned with establishing which bidder believes that they can do a task using the least amount of energy. Thus the Vickrey auction is not different in the context of this thesis from the Dutch auction. As it performs nearly identically to the Dutch auction, it will provide no special benefit, and will require less communication that the English auction, but more than the First-Price, Sealed Bid auction.

Thus in the context of this project, no auction type provides any significant benefits over any other type of auction, but using the First-Price Sealed Auction will require less communication and also requires less effort to implement.

## E. Use of Contract Net Protocol in Robotics

The use of Contract Nets for controlling multi-robot systems was really established in [19] in response to a criticism that "[Negotiation] solutions have not been adequately demonstrated in situated agent (i.e., robotic) teams, which have to live in and react to dynamic and uncertain environments amidst noisy sensors and effectors, frequent agents failures and a limited bandwidth, noisy communication mechanism" [20]. The problems described in this criticism are indicative of an apprehensiveness to use negotiation solutions, such as the Contract Net Protocol. This has limited the use of the Contract Net Protocol in multi-robot systems.

More generally, the benefit of using a market economy for controlling the exploration of a robot system was studied in [18], in which is was found that robot systems that did not communicate had an exploration coverage efficiency that was only $29 \%$ of one which
used a market economy for controlling exploration. However it was not specifically using a Contract Net System, and did not investigate using an adaptive system for negotiations or bidding.

## F. Neural Networks

The general problem of task distribution is exponential in complexity (NP-Complete) [21]. Artificial Neural Networks have been shown to provide feasible solutions to some NP-Complete problems [22].

Neural Networks originated in the branch of artificial intelligence that tries to make computers think like humans. The basic unit of a neural network is the neuron. A neuron has several inputs, which are individually weighted. An input function sums the weights into a single value, and this value acts as the input to an activation function (typically non-linear), which determines what values should be provided as output values. Each of these output values in turn will typically go to other separate neurons and act as inputs for other neurons.

There are two main types of neural networks, the feed-forward (acyclic) neural network and the recurrent (cyclic) neural network [23]. In recurrent neural networks, there is no end point to the network, but after data goes through the "last" neurons, the outputs for these neurons become the input values for what had been the first neurons, thus
producing a cyclic pattern. This type of network is extremely complex, so feed-forward neural networks are more commonly utilized, which is the case for this thesis.

A feed-forward neural network when given a set of input values, will calculate a set of output values. As the data passes through each neuron, a weight is applied to it, and it is combined with other weighted pieces of data, and a function is applied to this combined value. Eventually some neurons will be reached whose outputs do not serve as inputs to other neurons. The outputs from these neurons are the outputs of the neural network. These values may be incorrect though. One main reason for this is because the weights applied to each input may be completely wrong, and almost always are initially as they are customarily random values to start with. They are random values to start with because initially it is impossible to know what the correct weights should be set to and yet at the same time is has been found that the initial weights must not be equal [22]. This then implies the need for a way to adjust the weights, and such a method for adjusting weights exists and is called back-propagation.

There are two main stages of establishing a feed-forward neural network: training and testing. In the training stage, inputs are given to the neural network, and the neural network produces output values. The correct output values for each piece of training data are known. The network is given the correct output and it is able to calculate the error between the values that it produced as output versus the actual known output values. Back propagation involves using this error in conjunction with formulas derived from
energy and momentum in physics to adjust the weights so as to try to produce more accurate outputs.

The network goes through the cycle multiple types of using the training data as inputs, finding an error value when compared to the actual known outputs, and adjusting the weights. This cycle is usually done several hundred times in order to get the weights to stabilize, so that additional cycles will produce very little change in the values of the weights. In some cases, the weights never stabilize sufficiently.

After this, the neural network is given inputs from the test data, and it produces output values. The actual known outputs for the test data are not given to the neural network, but are instead compared with the values that are outputted, so as to assess the efficacy of the network in determining the output values.

Even after all of the adjustments to the weights are done during the training process, there is no guarantee that the neural network will produce the correct outputs during testing. If the weights have stabilized, there is the possibility of the network having memorized the training data instead of having generalized it (finding the descriptive patterns in the data).

If the weights have not stabilized, the network may in fact work well with the test data, but it may not. If not, then the architecture of the neural network may be at fault. The ability of a feed-forward neural network to learn patterns is held in the weights involved in the neural network. These weights are on each connection between each neuron in the
neural network. If there are too few neurons, there are too few weights with little capacity for learning a pattern [27]. Too many neurons may be prone to memorization.

As the feed-forward neural network is not cyclical, there are layers of neurons, with one layer's outputs being the inputs of another layer. There are at least two layers, an input layer, that accepts the input values to the neural network and an output layer that outputs values from the neural network. Using only two layers limits the neural network to only linear models [25]. More often, one or more hidden layers are used which allows for nonlinear models [26] by providing greater computational ability, as well as providing more weights in which patterns may be learned. There may be multiple hidden layers, with each having different number of neurons. The number of hidden layers combined with the number of neurons in each hidden layer affects how complex a pattern the neural network can learn.

The extremely complex and random nature of neural nets means that there is no way to know what the optimal network architecture (number of hidden layers and number of neurons in each) should be [24]. The determination of what network architecture to use involves a great deal of trial and error. While the unpredictability involved in determining the architecture of a Neural Network may seem like it would make Neural Networks useless, it is at the same time this very nature that makes them very useful, in that they can sometimes provide excellent quick approximations of non-linear systems that would otherwise take exponential time to compute. It is for this reason that neural networks
were used in this thesis, with inputs being a path and outputs being expected energy and damage.

## 3. Methodology

## A. Tools

There were two main steps for evaluating the tools to be used in this project. The first step was the selection of a robot simulation package, followed by the selection of a neural network software package.

## I. Robot Simulation Platforms

A premise of the experiments was that the robots share a level of communication between robots that is not yet readily available. Given this, it was decided to implement the experiment on a robot simulation software platform. Several different platforms were considered in depth for use.

The criteria used for considering a platform were (1) the difficulty involved in implementing a foraging scenario (2) the availability of quality documentation and (3) the availability and ability to use existing neural network software in conjunction with the robot simulation platform.

A number of platforms were considered, but ultimately three platforms emerged as the main candidates for use: TeamBots [7], Gun-Tactyx [8], and Robocode [9].

## a. TeamBots

TeamBots is a well known robot simulation platform, allowing simulated robots to be written in Java (with some C as well). TeamBots offers significant flexibility in simulating a large number of environments. Significant amount of work is required to set up an environment in TeamBots. TeamBots however has not been updated since 2000 and over time documentation for it is has disappeared and fallen apart, rendering it extremely hard to learn.

Figure 1: A simple robot simulation in TeamBots.

## b. Gun-Tactyx

Gun-Tactyx is the newest of the three main robot simulation platforms that were considered and unlike TeamBots and Robocode which are two dimensional (2D) simulations, Gun-Tactyx is a three dimensional (3D) simulation. Although it was originally conceived as a simulation of robots battling each other, it offers significant flexibility and has been extended for uses such as robot soccer. However, it is not well documented; compounding this was the problem that it required that robots be written for it in a non-standard language. This would have precluded the use of existing neural network software.

Figure 2: A robot simulation in Gun-Tactyx.

## c. Robocode

Robocode is the robot simulation platform that was ultimately chosen for use. It is a robot simulation package intended for simulating robots battling each other. It was started by Mathew Nelson at IBM [6]. After being maintained by IBM for several years, it was made into an open source project [28], and continues to be regularly updated.

One major drawback to using Robocode was that it was less flexible than either TeamBots or Robocode in allowing a foraging scenario to be implemented, instead of a combat scenario. Robocode is implemented in Java, and robots are written using a well documented Java API [29]. The use of a major language and level of documentation allowed for a foraging scenario to be implemented, but not to be displayed graphically.

Robocode is implemented purely in Java, and the robots are also written in Java. As Robocode was the only platform of the three that was both fully implemented in a single, major language and also had robots which were implemented in a single, major language, Robocode seemed most likely to work well with already existing neural network software. Unfortunately, it was later found that because of security features built into Robocode, it was harder to use existing neural network software than was originally thought, although it was accomplished.

Figure 3: A simple view of robots in Robocode.

## II. JOONE

After the Robocode was selected as the robot simulation platform, a search of available neural network packages implemented in Java was conducted. The search revealed that there was one popular, maintained, well documented, powerful and flexible neural network software package available. This package is called the Java Object Oriented Neural Engine (JOONE) [30].

A number of available Java neural network packages are GUI based only. While JOONE does allow for setting up a neural network via a GUI, it also allows for a neural network to be set up via a Java API. Additionally, not all Java based neural network packages are free and allow for alteration of the code that runs the neural network. JOONE is Open Source Software, which became an important factor as some adjustments to the code were necessary to permit the code to run in conjunction with Robocode.

## B. Experiments

There were two main phases to conducting the experiments. The first was setting up the foraging environment and the second was developing the programs that guided the robots behavior.

## I. The Map

The map used was of size 1000 pixels by 1000 pixels, with robots being 18 by 18 pixels in size.

The map consisted of three parts: (1) a home base at which robots can return to drop off food and restore their energy reserves, (2) food sources with limited amounts of food that can be collected from and eventually become depleted, and (3) obstacles that slow down the robot, or damage parts of the robot. In this thesis we consider obstacles to be rough terrain that may slow down and damage a robot, but does not completely stop a robot.

A small program was written that randomly placed specified numbers of food sources and specified numbers of obstacles on the map. Each map was written to a file, and loaded for experimentation with different kinds of robots and varying numbers of robots.

## a. Food Sources

In the foraging problem, robots must collect food. Food sources were implemented as randomly placed points throughout the map. Each food source starts with a randomly selected amount of food between 0 and 5 (continuous) units. Robots can collect up to 1 unit of food, but the amount of food collected is often less because a robot's ability to collect and carry food can be damaged, resulting in the ability to collect less food than this. Additionally, robots may be already carrying a partial load of food (such as if the robot went to another food source and the food there ran out), which would reduce the amount of food that the robot can collect from another food source. Once a food source has been depleted by having the amount of available food reduced to 0 , that food source is ignored by the robots.

## b. Obstacles

The experiments involve a team of robots' ability to not only decide what food sources to select from, but also to get to those sources of food, and preferably via a path that uses less energy and causes less damage.

When a robot attempts to go through an obstacle, the robot is temporarily slowed down by an amount depending on what type of obstacle is involved. In addition there is a chance that the robot may suffer permanent damage. There are three types of damage that
a robot may suffer: (1) damage to the engine, (2) damage to the scanner, and(3) damage to the food collector. When a robot suffers damage to the engine, the robot will take longer to cover a specified distance than when not damaged. In addition, more energy will be used to travel this distance. Eventually a robot's engine may become so damaged that the robot becomes disabled and unable to move. When a robot's scanner becomes damaged, the distance at which it can spot a new food source is reduced. When a robot's collector becomes damaged, the amount of food that a robot can collect and carry is reduced.

There are four types of obstacles: mud, sand, thick brush, and snow. Mud results in high chance of engine damage, medium chance of scanner damage, and low chance of collector damage. Sand results in medium chance of engine damage, medium chance of scanner damage, and medium chance of collector damage. Thick brush results in medium chance of engine damage, medium chance of scanner damage, and high chance of collector damage. Snow results in low chance of engine damage, medium chance of scanner damage and medium chance of collector damage.

## II. The Robots

Three different robots were simulated to work in a foraging environment. These were:

- A basic robot
- A robot that uses a contract net without adaptive bidding (using a first come-first serve strategy)
- A robot that uses a contract net with adaptive bidding (using a neural network to estimate the amount of energy required and probable damage)

## a. Teams

In order to compare the performances of each type of robot, homogeneous teams of robots were simulated operating in identical environments, where only the starting positions of the robots were changed. The reason for the change in starting positions is that robots in Robocode are placed in random locations at the beginning of each simulation. To account for this, averages were found over 10-20 simulations for each type of robot, for each team size. At no point were robots of different types placed on the same team and at no time were multiple teams simulated at the same time.

The size of the robot teams was varied from three to fifteen robots. Each robot in Robocode is run as its own thread. Each robot that used adaptive bidding used the JOONE neural network package, in which each node is run as its own thread. For these reasons, when using adaptive bidding, there was an explosion of threads trying to run at the same time. Thus memory problems arose when using more than 15 robots.

## b. Communication

A current problem in mobile robotics that particularly affects the Contract Net Protocol is limitations in the communication capabilities between robots [1][8][10]. In this thesis, we relaxed the current practical communication problems in the view of examining the usefulness of using the Contract Net Protocol with adaptive bidding at some point in the future when communication capabilities between robots have been improved. In the
experiments, Robocode's built in communication tools were used that allow a robot to communicate with any other robot that is on the same team, or allow a robot to communicate with every other robot that is on the same team (broadcast).

## c. Criteria for Success

There are several different criteria used for judging the success of task allocation problems. Gerkey and Mataric [11] considered there to be two different criteria, quality and cost. One measure of cost is often the amount of energy expended in completing a task.

Quality can be less defined and may have task specific definitions, such as in the case of the foraging problem, the amount of food gathered can be considered part of the quality. Time required for completion of a task is also sometimes considered part of the quality of a completed task [11], but can also be considered part of the cost of task completion. In the case of this thesis, we consider it as a separate criterion from the cost (energy expended), or quality (which is task dependent). In the experiments we are imposing a time limit on each simulation so as to be able to perform numerous simulations. This means that time could not be used as a criterion for success.

Therefore, energy consumption and the amount of food gathered are used as criteria for success. There are a number of cases in which success may be considered. There is individual robot consideration, in which a robot evaluates its own performance after a task has been completed, so as to be able to then determine how it should bid in the
future. There are also end-of simulation considerations. In end-of simulation considerations, all experimental data is known, and conclusions can be drawn for a specific task as to whether it is better to maximize time or energy, or find a threshold for tradeoff. However there is an initial paradox for individual robot's considerations. Individual robots during simulation will not know whether energy or food is more important. For this reason, it is best to have robots heuristically try to maximize only energy or food. For this project, robots will be attempting to maximize food gathered.

## d. Basic Robot

A basic robot was created as a control group. This robot followed a greedy strategy with no task allocation strategy, but with information sharing.

For a fair comparison of robots, all robots should have the same capabilities, including communication. This means that reasonable communication can be established between the basic robots. Sharing of information about food source locations was included as it was thought likely to improve team performance without having a task allocation strategy.

Initially, the basic robots do not know where food sources are. The first task of the basic robot is to explore the map searching for food, until it finds a food source to collect from.

Once a food source is found, the location and amount of food at the food source is communicated to other robots, and food is collected. If the food source has more food than the robot can carry, then the robot will take as much food as it can carry and proceed
back to the home base. If the robot is able to carry more food than can be collected from the food source, the robot takes the available food and communicates to other robots that the food source has been depleted. In this case, if the robot knows of other food sources, it will proceed to another food source and will collect food from there. If the robot does not know of other food sources, then the robot will again search for food sources.

At every point in which the robot travels, an estimation is made of how much energy the robot requires in order to return to the home base. This estimation is based upon the Euclidean distance between the robot and the home base, with a multiplier included to help account for obstacles. Certain energy is needed to account for the time needed for making the calculation and responding to the calculation. If at any point the robot's energy level drops below this estimated energy level, all other actions of the robot are suspended and the robot immediately heads to the home base, regardless of whether the robot is searching or going to a known food source.

Every time a robot returns to the home base, it determines what its next task should be, whether searching for new food sources, or collecting food from a known food source. The basic robot follows a greedy strategy and will collect food from the closest food source.

While collecting food or returning home, a robot may encounter previously unknown food sources. In this case, the robot will record the location of the food source; and it will alert other robots as to the location of the food source and amount of food it contains. If
the robot is returning home, then it will continue returning home, and after that if the discovered food source is the nearest food source, then the robot will collect from there. If the robot is on its way to collect food from another food source, the robot will continue to that other food source. Upon the robot returning to the home base, or the robot depleting the food source and being able to carry more food, the robot will determine the nearest food source, which may be the newly discovered food source, and will collect food from that food source.

While exploring, collecting food, or returning home, a robot is continually scanning for obstacles in its path. For the basic robot, when an obstacle is found ahead, the robot will look towards the left, and look towards the right. If in either direction, there is no obstacle, then the robot will proceed in that direction for a distance and then the direction needed to get to its destination, if known. If an obstacle is observed in both directions, then the robot assumes that there is no better path to its destination, so proceeds forward in the original direction.

Additionally, robots can take damage from running into the walls surrounding the environment, and from running into other robots. When the robot detects a wall in its path, it slows down or stops and readjusts its direction. Similarly, when a robot detects another robot in its path, it will slow down or stop, then changes direction to the left to try to go around the robot. This is a form of 'social law' that allows robots to generally avoid each other [31].

## e. Contract Net Without Adaptive Bidding Robot

Another type of robot that was developed was a robot that uses the Contract Net Protocol to coordinate tasks among robots, but without adaptive bidding.

Initially, robots of this type have no knowledge of food sources, so similar to the basic robot, they begin by exploring the environment until a food source is found.

Upon finding an unknown food source while exploring for food, a robot communicates to other robots the location of the food source. Other robots consider that food source as belonging to the robot that discovered and communicated the location of the food source. These other robots will not forage food from this food source. The robot that discovered the food source will then forage food from this food source.

When while collecting food or returning home a robot discovers an unknown food source, that robot will communicate to other robots where the food source is. Other robots then will not forage food from this food source. As the robot is in this case working on foraging from another food source, it will continue to collect food from the food source that it had been collecting from, not from the newly discovered food source. The robot will however let other robots know that it has a task to be performed by other robots and invites other robots to bid on the task. If another robot is in the act of searching for a food source, it will bid on the task. For robots that used the contract net without adaptive bidding, the robot that discovered the food will accept the first bid that it receives.

Just as robots that find new food sources while harvesting from other food sources do not abandon their original tasks, robots do not give up on a task that they have been given by another robot. That is to say that after a robot has accepted a contract, it may not decommit [35] [36] from that contract.

If a robot is foraging from a food source, and discovers a new food source, it will advertise for bids for the task of foraging from the newly discovered food source. This does not mean that the robot will necessarily receive any bids for the task. If the robot depletes the food from the food source it is currently working on, i.e., it finishes its task, if it has discovered a food source and advertised for bids, but not received any and given the task to another robot, then the robot that discovered the food source will start collecting from that newly discovered food source and will no longer advertise for bidders for the task.

As with the basic robot, the robot that uses the Contract Net Protocol without adaptive bidding continually keeps track of an estimate of the energy level at which if the robot drops significantly below this level, it may not have enough energy to return home and replenish its supply of energy. Just as was the case with the basic robot, if at any time the robot's energy level drops below this estimate, the robot will immediately suspend its current activity and proceed home.

The robot that uses the Contract Net Protocol without adaptive bidding behaves in the same way as the basic robot when the robot detects a wall or robot ahead.

## f. Contract Net With Adaptive Bidding Robot

The final type of robot developed was the robot that uses the Contract Net with adaptive bidding. Similar to the basic robot and the robot that uses the Contract Net Protocol without adaptive bidding, the robot that uses the Contract Net Protocol with adaptive bidding starts without knowledge of where food sources are located, and has an initial task of exploring the environment to try to find new food sources.

Once a new food source has been found, the robot that discovered the food source sends out a message to other robots alerting them to the location of the new food source. The other robots then will not take food from that food source, just as with the robots that did not use adaptive bidding. If the robot that discovered the food source was searching for food, then that robot will take the task of collecting food from that food source. If the robot that discovered the food was collecting food from another food source at the time, then that robot will continue collecting food from its original food source and will advertise for bids from other robots on the task.

## III. The Bidding Process

The robot that uses the Contract Net Protocol without adaptive bidding accepts the first bid that it receives. With adaptive bidding, bids have values that reflect how efficiently
the robots that make the bids believe that they can carry out the task. Since there can be differences in the bid, the robot that advertises for bids will have to consider multiple bids. However, since the robots are run in separate threads, there can be some variance in the amount of time it takes for a robot to process a bid request and send a bid. For this reason, when using the Contract Net Protocol and not giving the task to the robot that sent the first bid, one of two strategies must be employed for determining when to stop accepting bids: (1) placing a time limit after which the robot with the best bid is awarded the contract to do the task, or (2) establishing a threshold (a reserve price in the auction terms) for which the first bid to meet the threshold is awarded the contract. Often there is a time limit built in as well, in case no bid meets the threshold. In order to establish a threshold however, a robot needs to be able to estimate a reasonable cost for accomplishing a task, which requires knowledge about other robots. Thus, in order for a threshold to be used, the robot requesting bids must have significant knowledge of the likely cost of accomplishing a task. Yet it can not be assumed that any robot has such significant knowledge. In fact, the collective knowledge of the robots offering bids is likely to be greater than the robot requesting a bid, and so it will be better to only use bids with a time limit without using a threshold. In this thesis a robot that uses the Contract Net Protocol with adaptive bidding that request bids waits 300 milliseconds for bids to be submitted. At the end of this time, the robot that requested the bids sends a message to the robot with the best bid, informing it that it has been given the contract to carry out the task. When a robot submits a bid, it waits for 300 milliseconds. If it has not received a message indicating that it has been awarded the contract, then it continues searching for
new food sources or submits a bid for a new contract. A robot may not have two bids submitted at the same time.

As the robots are assumed to be honest robots, and they are ultimately homogenous, each robot that contracts out a job has no need of knowing the exact capabilities of robots that submit bids, but only needs to concern itself with finding the best bid. This allows for robots that only have knowledge of their own individual problems, without need for greater knowledge of the social system as a whole [32][33][34].

## IV. Formation of Bids

Obstacles affect how efficiently a robot can carry out a task, whether from requiring more energy to go around an obstacle, or requiring more energy to go through an obstacle, as well as sometimes damaging robots that go through obstacles. This damage also affects how well a robot can carry out its tasks.

Initially however, robots using the Contract Net Protocol with adaptive bidding have no knowledge of where the obstacles are or what types of obstacles they are. This means that initially these robots cannot make reasonable bids. For this reason, robots initially revert back to the behavior of the robots that use the Contract Net Protocol without adaptive bidding, with robots that have requested bids awarding contracts to the first robot to make a bid. After a robot has gathered knowledge on 10 'paths', it assumes that other robots have likely gathered some initial knowledge of the environment as well, and thereafter the robot switches to waiting after sending out bid requests and accepting the best bid as
opposed to the first. Furthermore, the bid request is altered to indicate to other robots that only robots with this basic knowledge of the environment should submit bids.

For determining paths, a robot starts by making a record of its state, including its position, energy, level of damage, and current speed. After the robot has traveled a short distance, its new position, energy, level of damage, and current speed are recorded and compared with the earlier records. After 10 such paths were recorded, a neural net was trained with these 10 paths as training data. The coordinates acted as input data, while the rest of the data acted as expected outputs. In this way, the neural net was trained to try to learn about the environment, i.e., learn the map.

The initial results did not show a clear improvement with robots set up using this approach. It was surmised that the cause of this was the neural network was trying to learn too many pieces of information. The robots were then altered to not use the levels of damage and current speeds as part of the expected output data, but instead to only use the difference in energy as the only piece of expected output data.

## V. Network architectures

In order for a robot that uses the Contract Net Protocol with adaptive bidding to have any potential to outperform a robot that uses the Contract Net Protocol, it must have the ability to adapt quickly to make reasonable bids. For this reason, numerous neural
network architectures were examined for use, starting with the simplest architectures, and progressing to more complex ones.

The initial type of network architecture had one hidden layer. The number of nodes in this hidden layer was varied between two and sixteen nodes.

Neural networks have a learning rate, which varies the rate at which the network tries to learn a pattern. The reason for this is to avoid cases where the network would try to learn too quickly and would be less likely to stabilize. "The convergence speed of backprop is directly related to the learning rate" [37]). The learning rates tested were $0.4,0.5,0.6,0.7$, and 0.8 . The best learning rate was found to be 0.7 .

Initial results were not especially promising, so a second layer was also used. When using two hidden layers, the number of nodes used for each hidden layer was varied between two and 10 nodes. The reason for the difference in the highest number of hidden nodes tested was because of the significantly higher number of weights involved when two hidden layers. For example, with four inputs, when using one hidden layer with 16 nodes and 5 output nodes, there are $4 \times 16+16 * 5=144$ weights. With four inputs, when using two hidden layers with 10 nodes each and 5 output nodes, there are $4 \times 10+10 \times 10+10$ x $5=190$ weights. Thus even though the maximum number of nodes per hidden layer when using two hidden layers is lower, the number of weights is larger than when using only one hidden layer. Additionally, each robot has its own neural network, further expanding the number of weights being kept track of, and each of these weights is
updated multiple times. For these reasons, the number of nodes has to be kept relatively low.

Additionally, the number of epochs (the number of times that errors were calculated and weights were adjusted), had to be kept moderately low in order for the network to be quickly trained. The number of epochs chosen was 200 , as this resulted in a quick training time.

Early results did not show significant improvements with a robot using the Contract Net Protocol with adaptive bidding through a neural network with 5 outputs over a robot that used the Contract Net Protocol without adaptive bidding. Initial analysis suggested that the network was being trained to try to learn too many outputs. The networks were altered to only have one output: the energy expended on a path. Networks with both one and two hidden layers were then reexamined.

## VI. Team Size

This thesis is ultimately an examination of team performance. One important variable then was the team size. The size of the teams were limited to a maximum of 15 robots because of memory limitations. The size was reduced incrementally by 3 robots.

Each network architecture was tested with each team size in order to examine how the architecture in conjunction with the team size affected the results.

## VII. Computing

This experiment was run on 2.8 GHz Pentium 4 with 1024 MB RAM on Windows XP, with Java 6(u1), Robocode 1.2, and JOONE 2.0 .0 RC 1 . Robocode has fairly strong security features which make using external packages somewhat difficult. Therefore JOONE had to be repackaged and some of the source files had to be adjusted to accommodate repackaging.

## 4. Experimental Results

## A. Basic Robot

Five team sizes comprising of robots of the basic robot type were used. The teams consisted of $3,6,9,12$, and 15 robots. Each team was simulated twenty times and the results were averaged together.

## I. Energy Usage

The energy was initially examined for the Basic Robot. One unit of energy is defined as the amount of energy required for a robot to move one pixel, when the engine is working at full capacity (no damage), and not in any obstacle (slowing down the robot).

Figure 4: Per Capita Average Energy Used for Basic Robots

The average amount of energy used by the teams with $3,6,12$, and 15 robots was very similar, with the amount of energy used by the team with 9 robots was slightly higher, but this can likely be attributed to simple variation and not necessarily indicative of a trend.

## II. Food Gathered

Food sources had between 0 and 5 units of food. A robot can collect up to one unit of food before having to return back to the home base. However this is a maximum amount, and the robot's collector may become damaged, which will reduce the amount of food the robot can collect from this maximum.

Figure 5: Per Capita Average Food Gathered for Basic Robots

There is a clear trend involved in the average amount of food collected by teams consisting of the basic robot, with the average amount of food collected being greatest when using the fewest amount of robots, and the average amount of food collected continually decreasing, with the team with 15 robots having the lowest average collected food. Observations showed that the greedy strategy of the robots, in conjunction with information sharing, led to robots concentrating in small areas and having difficulty moving around each other.

## III. Damage

The damage is a measure of the performance of the three main components, the engine, the scanner, and the collector. In Figures 6, 9, 14 and 17, damage is represented by the average performance of these three components at the end of the simulations as compared to the performance at the beginning of the simulation. For example, at the beginning of a simulation, it takes one unit of energy for a robot to move one pixel in distance. If the robot has an average end efficiency of $20 \%$ for its engine, then it will take 5 units of energy to move one pixel in distance at the end of a simulation. A $20 \%$ end efficiency for the collector means that a robot can only carry $20 \%$ as much food per load as when the simulation began. Similarly, a $20 \%$ scanner end efficiency means that a robot can only scan $20 \%$ of the distance ahead as when the simulation began.

Figure 6: Per Capita Average End Component Efficiency for Basic Robots

Figure 6 shows a high amount of variability, with few to no significant trends. This information is presented as it was originally thought that damage might be an important indicator of the success of a robot, although this was not found to be the case.

## B. Contract Net Without Adaptive Bidding Robot

## I. Energy Usage

Figure 7: Per Capita Average Energy used for Contract Net Robots (without adaptive bidding)

The energy usage again did not show significant trends for teams consisting of robots that used the Contract Net Protocol without adaptive bidding.

## II. Food Gathered

Average Food Gathered for Contract Net Robots (without adaptive bidding)

Figure 8: Per Capita Average Food Gathered for Contract Net Robots (without adaptive bidding)

In Figure 8, the average food gathered for teams consisting of robots that did use the Contract Net Protocol without adaptive bidding did once again show a significant trend. The average amount of food gathered decreased with greater numbers of robots, but plateaued once 9 or more robots were used on a team. There was a slight rise at 15 robots, but this may still be a part of the plateau, but just be a small random variation.

## III. Damage

Average End Component Efficiency for Contract Net Robots (without adaptive bidding)

Figure 9: Average End Component Efficiency for Contract net Robots (without adaptive bidding)

There seems to be a fairly high level of variation once again, with the level of damage to the Engine and Scanner being more stable than the level of damage to the Collector, with the damage to the Engine again being more severe than the damage to the Scanner. The amount of damage to the Collector showed was once again highly varied.

## C. Contract Net With Adaptive Bidding Robot

After the Basic Robot and the Robot using the Contract Net Protocol without adaptive bidding were tested, the robot using the Contract Net Protocol with adaptive bidding was tested. It used a neural network in order to adaptively formulate bids. Initially the network had 5 outputs: the energy consumed, the current speed, and the damage to the three components of the robot. Initial experiments showed that the number of nodes used in the hidden layers did have an impact on the amount of food gathered (as shown in Figure 10), although the addition of extra nodes increasingly varied the results.

Figure 10: Per Capita Average Food Gathered When Using 5 Output Nodes
In Figure 10 each line represents a certain number of nodes being used in the first hidden layer, while the x axis represents the number of nodes in the second layer, and the y axis
represents the amount of food gathered by robots using this network architecture. The amount of food is averaged for teams of each of the five team sizes.

Ultimately however, it could not be established with confidence that the robots using the best network architecture ( 6 nodes in each of the two hidden layers) was significantly different than when not using adaptive bidding. An initial suggestion was that this might be due to the network trying to learn too many different types of information, so the expected outputs were reduced to one piece of information: the amount of energy used.

Figure 11: Per Capita Average Food Gathered When Using 1 Output Node

The benefit of only using energy as the output was not a huge difference, but it was enough so that there was reasonable confidence in the performance of the best architecture ( 8 nodes in each hidden layer) over the performance of robots using the Contract Net Protocol without adaptive bidding.

## I. Using Five Output Nodes

First, the performance of robots using the best architecture (when using five outputs) is examined.

## a. Energy Usage

Figure 12: Per Capita Average Energy used for Contract Net Robots with 5 outputs and best architecture

As has been the case, the amount of energy used has not shown much of a trend, but at the same time it has kept generally kept within the 4,000-7,000 range. This is likely due to the time limit imposed on simulations. When a robot moves through rugged terrain, the robot is slowed down and expends more energy than would be the case if moving at that speed in clear terrain. If the robot does not go through harsh terrain, then it will likely get to its destination quicker and start moving toward a new destination, continuing to spend energy. Thus because the experiment is time limited and does not run until every bit of food is collected, the robots are constantly expending energy and the amount of food gathered is more indicative of success.

## b. Food Gathered

Average Food Gathered for Contract Net Robots with 5 outputs and best architecture

Figure 13: Per Capita Average Food Gathered for Contract Net Robots with 5 outputs and best architecture

One especially ominous sign for robots using the Contract Net Protocol with 5 output nodes was that although the amount of food gathered seemed to be higher than for when using robots without adaptive bidding, there was nonetheless a trend of each robot gathering less and less food when more robots were introduced.

## c. Damage

Figure 14: Per Capita Average End Component Efficiency for Contract Net Robots with 5 outputs and best architecture

In Figure 14, the amount of damage to the components was yet again wildly variable.

## II. Using One Output Node

## a. Energy Usage

Average Energy used for Contract Net Robots with 1 output and best architecture

Figure 15: Per Capita Average Energy used for contract Net Robots with 1 output and best architecture

The amount of energy used was consistent when using only one output.

## b. Food Gathered

Average Food Gathered for Contract Net Robots with 1 output and best architecture

Figure 16: Per Capita Average Food Gathered for Contract Net Robots with 1 output and best architecture

Although the amount of energy seemed to remain high, there was the benefit of the amount of food gathered being fairly high, and remaining fairly stable, with a plateau after a short drop between when 3 and 6 robots were used.

## c. Damage

Figure 17: Per Capita Average End Component Efficiency for Contract Net Robots with 1 output and best architecture

Although the amount of energy and food gathered seemed fairly stable when using one output, the end damage to the robots showed no such stability.

## III. Five or One Outputs

Average Food Gathered for a few select number of hidden nodes when using one and five
outputs

Figure 18: Per Capita Average Food Gathered for a few select number of hidden nodes when using one and five outputs

Figure 18 shows a few select points that show how initially, when using few nodes in the hidden layers, the performance difference between when using one and five outputs is quite small. As the number of nodes increases, the benefit of using only one output becomes more pronounced, however when the number of nodes rises further, although using one output ultimately produces the best results, there are more variability in the results so that in some network architectures it is better to use five outputs instead of one.

## D. System Comparison

## I. General Analysis

Figure 19: Per Capita Food Gathering Comparison for 3 Types of Robots

The performance of the basic robot suffered heavily as more robots were used. Observations indicated that this was a result of the greedy nature of the basic robot in conjunction with information sharing. This resulted in the basic robots tending to try to
gather food from the same food source, which led to heavy congestion with robots spending a significant amount of their time just trying to navigate around each other.

The robot that used the Contract Net Protocol without adaptive bidding started off very similar to the basic robot, but had far less of a performance drop as additional robots were used on the team. Observations suggest that this is due to robots not gathering food from each other's food sources, significantly reducing the amount of time robots spent navigating around each other.

The robot that used the Contract Net Protocol with adaptive bidding (7 nodes in each hidden layer with one output) performed the best. This included the beginning which is likely to just be a random variation, given that the results for when using more team members is fairly stable (albeit lower) and seems to correspond to the starting level.

## II. Statistical Analysis

An ANOVA test was used (Figure 20) and showed with $95 \%$ confidence that the results from the three robot types were not the same. It also showed with $95 \%$ confidence that the results from teams of robots of different sizes were not the same. It lastly also showed with $95 \%$ confidence that the combination of robot type and team size made a difference in the results.

## 5. Conclusion

## A. Contributions

This thesis first confirmed the findings of [19] in showing that the use of the Contract Net Protocol is both practical and beneficial in multi-robot systems. The major contribution of this thesis however was demonstrating the importance of bid formulation when using the Contract Net Protocol in multi-robot systems and showing that system performance can be enhanced by using adaptive bidding through use of neural networks. Additionally, this thesis showed the need for a social control mechanism when using improved communication and demonstrated the benefit of using on such mechanism, the Contract Net Protocol. Finally, this thesis showed that when using a neural network for adaptive bidding with the Contract Net Protocol in a time limited setting for foraging, a neural network provides the most benefit when concentrating on energy.

## B. Benefits of Contract Net

There are several benefits of using a Contract Net for controlling a group of robots. The first is that some sort of social order must be established for who has permission to do what. Although when there are only a few robots, such order makes little difference, as the number of robots increases it becomes critical to have some such semblance of order, otherwise a series of robots is prone to heavy congestion, drastically reducing the efficacy of the individual robots, and the system as a whole. The order imposed by the Contract Net Protocol may seem like a limitation at first from the perspective of the individual
robot. From an individual robot's perspective, it will often limit the robot from gathering from the closest food source, which from the robot's perspective is usually going to be the best choice. The robot will then wind up gathering from a less desirable food source. However because of the structure involved, that limits not only that one robot, but all the other robots, the individual robot nonetheless ultimately benefits, as does the system as a whole.

There are more benefits to using the Contract Net Protocol other than simply the social organization. When using adaptive bidding, the Contract Net Protocol is a full auction system. Although the performance benefit between when using the Contract Net Protocol with adaptive bidding and using the Contract Net Protocol without adaptive bidding was not as large as the performance benefit between using the Contract Net Protocol without adaptive bidding and using the basic robot, there was nonetheless a definite benefit as robots were given tasks for which they were slightly better suited than their fellow robots.

As it stands today, the benefit of using the Contract Net Protocol in robotic teams may be rather small because of the large communications requirements of the protocol. In the future however, when greater bandwidth and more reliable communications between robots is commonplace, the Contract Net Protocol can be a suitable task allocation strategy for autonomous mobile robots.

## C. Neural Network Architectures

Although it has been shown here that adaptive bidding does increase the performance of a team of mobile robots that uses the Contract Net Protocol, setting up a neural network that can adaptively form good bids is difficult even in a simulated environment.

There are issues of uncertainty that mean that the network is being trained with inconsistent data. For example, in these experiments a robot suffered damage only some of the time it went through an obstacle. This means that the results indicating which network architecture was best may not be entirely accurate, despite being run multiple times. The best architecture may have to some degree simply lucked into good results, while an architecture that seemed to perform more poorly may have simply had some back luck.

This is the nature of neural networks. While they can be designed so that they generally perform well for a particular problem, the performance can almost never be guaranteed. In particular, the more complex a neural network is, the more potential problems can be encountered by the neural network. With a more complex simulation or an actual robot, the neural network is likely to have to be more complex and finding a good network architecture will take significant time. In addition, the usage of a neural network will preclude being able to guarantee the performance of a team. While a team using the Contract Net Protocol with a neural network used for adaptive bidding may generally perform quite well, there may be cases in which it can perform poorly.

Furthermore, neural networks are currently relatively computationally expensive. At present it would be extremely expensive to create such teams of robots with sufficient computational power to run a fairly complex neural network. This however is a problem that will likely change in the relatively near future, almost certainly before the communication needs for such a team of robots can be satisfied. Current trends are to improve computational power by using multiple processors. This could be ideal for neural networks because the computations for the nodes in a layer of a neural network can be done in parallel, meaning that cheaper multiple processor systems will greatly increase the usability of neural networks in robot systems.

## D. Effects of Adaptive Bidding

When these experiments were being planned, it was expected that the inclusion of adaptive bidding would make a significant difference. However, a moderate performance benefit was achieved and it was not nearly as large as initially suspected. The larger issue turned out to be a need for some sort of social control mechanism for the robots. Such a social control mechanism will certainly be needed for teams of robots, but usage of a social control mechanism, namely the Contract Net Protocol, in conjunction with adaptive bidding is certainly going to provide better results.

Computational limitations limited the number of architectures that were tested, and it is quite possible that with further resources, adaptive bidding could provide even better results. The results of using adaptive bidding were sufficient to show that a definite benefit can be obtained by using adaptive bidding.

## E. Issues with Better Communication

Chief among the unanticipated results of this experiment were the implications of better communication among robots. The assumption of fairly reliable communication that supported moderately high bandwidth communications entailed information sharing among robots. This information sharing really required a social control mechanism among robots in order for robots to not mob a select few food sources.

A number of real world analogous situations can be applicable here, for example in cases where on the news it is announced that a certain gas station is selling gas for much cheaper than competitors (it has on rare occasion been known to happen). This announcement on the news alerts a large number of people, who examine the perspective from their own perspective and see a personal benefit to going to this gas station in expectation of getting cheaper gas. Yet this situation will likely cause a flood of people to go to this gas station, causing numerous problems including significant traffic congestion.

Ironically, it may be the case that systems that do not use a social control mechanism such as the Contract Net Protocol may benefit from not having better communication. If fewer robots know about a good food source, then there will be less congestion resulting from such numerous robots trying to access this food source, while other robots will congregate around food sources that are in closer proximity, even though these food sources may not be quite as appealing.

Better communication among robots is almost certainly going to become a reality at some point. This in turn will necessitate social control mechanisms, and the Contract Net Protocol has shown itself to be a promising such mechanism, which can be improved by using adaptive bidding. Thus the use and further research of adaptive bidding is a necessity that cannot be ignored.

## F. Future Work

There are a number of areas in which this work can be expanded. Unfortunately one such prime area is to test this approach on actual robots, but because of the assumptions made, this is impractical at the present. Nonetheless, a time will come in which these experiments can be run on actual situated agents. Until that time however, there are some adaptations that can be made to the simulation.

One such adaptation that can bring the simulation closer to real robots would be to use multiple computers for the simulation, having each simulated robot be controlled by a separate computer. This would allow for more complex network architectures to be experimented with.

Furthermore it would be extremely interesting to see the effects of using heterogeneous network architectures. In this experiment, teams using the Contract Net Protocol with adaptive bidding consisted only of robots with the same number of nodes. There is no guarantee that this is the best way of having a team use adaptive bidding, and it is possible that having multiple network architectures would alter the bidding process and
that alteration may be an improvement.
